Energy restriction, the basis for successful ageing in man?

Erica J.M. Velthuis-te Wierik and Henk van den Berg

TNO Nutrition and Food Research Institute, Zeist, The Netherlands

ABSTRACT

Restriction of energy intake (ER) without essential nutrient intake deficiency retards ageing and extends life span in various animal species. Although several potential mechanisms have been put forward, the mechanism behind this phenomenon remains unknown. This review describes the effects of ageing and energy restriction on three physiological systems (energy expenditure, free-radical activity and endocrine regulation) that are involved in the metabolic adaptation to ER and that seem to play an important role in the ageing process. Since ageing is a general biological phenomenon it seems likely that ER has the same beneficial effect on the ageing process in man. This article summarizes the effects of ER and ageing on these three physiological systems in both animals and man and attempts to explore the potential application of ER in man.

INTRODUCTION

The phenomenon that restriction of the intake of energy while maintaining the intake o adequate amounts of essential nutrients can retard ageing and extend life span has been firs discovered in the thirties by McCay et al.[1] Since then similar results have been observe in a great variety of animal species such as rats, mice, fish and flies (for reviews see[2,3] Moreover, energy restriction not only retards ageing but also prevents or delays the onse of many age-related diseases in animals.[4]

The mechanism through which energy restriction modulates the ageing process i unknown and is difficult to assess as determinants of the ageing process itself have not ye been identified. The physiological systems involved in, or affected by, the metaboli adaptation to energy restriction seem to play an important role in the ageing proces: Reported effects of ageing and energy restriction on metabolic rate, the neuroendocrin system and oxidative stress, i.e. free-radical production and scavenging capacity, are at lea: suggestive of common or integrated modes of action.

In this article the effects of energy restriction and ageing on these three physiologic systems will be summarized and discussed. It is beyond the scope of this article to revie all studies and reports published on the mechanisms and physiological systems involved i the intriguing, but very complex, relationships between metabolic adaptation, energ restriction and ageing. In this article we present the 'state of the art' and discu: experimental studies to explore the potential application of energy restriction in mai stimulated by the ideas of Weindruch and Walford[3] and their suggestions for a dietai regimen of 'undernutrition without malnutrition'.

THE EFFECTS OF AGEING AND ENERGY RESTRICTION ON ENERG EXPENDITURE

The basal metabolic rate (BMR) is defined as the rate of energy expenditure in a subje who is fasting and completely relaxed in a thermoneutral environment. In practice, tl resting metabolic rate (RMR), in the postabsorptive state and physically at rest, is usual the best approximation of the BMR that can be achieved. The terms are us interchangeably here.

Ageing and energy expenditure
Ageing is associated with a decline in RMR.[5-8] Some studies indicate that this decline mainly due to the loss of fat-free mass (FFM) with age,[9,10] but others demonstrated significant effect of age on RMR which is independent of the loss of fat-free ma

(FFM).[11,12] Since these contradictory findings might be a consequence of different levels of physical activity in elderly people, Poehlman et al.[12] compared RMR in sedentary younger and older men with individuals of similar age who regularly participated in aerobic exercise. Besides an age-related decline in RMR (which was independent of FFM) it was noted that regular physical activity diminished this age-related effect.

Thus, with ageing, BMR is reduced in the elderly and this decline is largely, but probably not totally, due to the age-related fall in fat-free mass. The fall in FFM and BMR with age might be attenuated by regular physical exercise.

Effects of energy restriction on energy expenditure
Animals

Sacher[13] proposed that energy restriction influences the ageing process by reducing the metabolic rate, i.e. by reducing 'the rate of living'. McCarter et al. studied BMR in rats after restricting their energy intake for 6 months,[14] and during their total life span.[15] They did not find a difference in metabolic rate per kilogram fat-free mass between male Fischer 344 rats fed ad libitum and rats on a food-restricted regimen (40% reduction). These findings suggest that energy restriction does not lower the metabolic rate per unit of metabolic mass. This negative answer to the question 'Does food restriction retard ageing by reducing metabolic rate?' has been criticized by Lynn and Wallwork.[16] In their opinion, the problem with McCarter's calculation is that they related oxygen consumption to fat-free mass rather than to functional metabolic mass. Lynn and Wallwork hypothesize that the flow of electrons to oxygen must be faster through the metabolic mass of the animals fed ad libitum, since the amount of metabolizing tissue in both ad libitum fed and restricted animals was calculated to be approximately equal but oxygen consumption was higher in the ad libitum fed animals.

As contrasted with McCarter's finding, Ballor[17,18] observed in obese male and female Sprague-Dawley rats a decrease in 23-hour and in resting oxygen uptake after 11 weeks of moderate (−25%) and severe (−50%) energy restriction. When corrections were made for body weight, moderate restriction had little effect on metabolic rate, whereas more severe deprivation lowered metabolic rate, even when metabolic rate was expressed per $kg^{0.75}$, one of the methods commonly used to correct for the reduction in metabolic rate that occurs as a consequence of the loss of body mass alone.

As indicated, changes in body composition, i.e. functional metabolic mass rather than FFM, play an important role in the change in BMR. However, since accurate measurements in vivo of functional metabolic mass are not yet available, one can only use FFM as an indicator. A decrease in FFM leads to a decreased BMR. Therefore, loss of FFM during periods of energy restriction should be minimized. From these animal studies it seems that energy restriction lowers metabolic rate due to the loss of FFM. However, more severe

energy restriction (50%) in adult rats may lead to a more efficient metabolic rate, i.e. a larger decrease in BMR than can be explained by the loss of FFM, which probably reflects reduced functional activity.

Man

One of the first experiments into the effects of energy restriction in man has been performed by Keys et al. in the early 1950's.[19] In their Minnesota Experiment, in which 32 healthy men received 50% of their habitual intake (semi-starvation), the investigators demonstrated that BMR decreased during semi-starvation. After 24 weeks of semi-starvation mean oxygen consumption had decreased by 38.9%, per square meter of body surface by 31.3%, per kg of body weight by 19.5% and by 15.5% per kg 'active tissue' (active tissue = body weight – (extracellular fluid + fat + bone mineral)). At the end of the experiment there was no further change in BMR, indicating that a new equilibrium had been reached.

Most of the more recent experimental studies into the effects of energy restriction on energy metabolism have been performed in obese people. In several studies a very-low-caloric diet (1,380-4,180 kJ/day) during a few weeks resulted in a decreased BMR.[20-2] Except in one study,[20] this fall in BMR was still significant when expressed per kg body weight or per kg FFM. In longer-term studies (12-48 weeks) in obese subjects an absolute reduction in BMR has been found[23-27] although in most of these studies these reductions were no longer statistically significant when expressed per kg body weight or per kg FFM.[23,25-27] These experimental studies suggest that in obese subjects energy restriction leads to a decreased BMR and that over a short period this decrease may be due to a decreased metabolic activity of the tissues, but that in the long run the loss of body tissue contributes to the lowered BMR.

In people on a habitually low energy intake the reduction in BMR may be in the order of 10%.[28] In an epidemiological study into the relationship between RMR and different parameters of body size it has been observed that, per kg FFM, RMR in the obese was higher than in normal-weight subjects,[29] but after weight loss this RMR seems to be similar to that of women who have never been obese.[30] These epidemiological results suggest that obese persons may be less efficient in energy utilization. Shetty and Soares[31,32] observed in chronically undernourished labourers with a lower daily energy intake than the age-matched control group, that the average BMR was lower in the undernourished labourers in absolute terms, but also per kg body weight per day, per kg FFM per day and per unit body surface area. From this study, Shetty concluded that a decreased body weight, adjustments in physical activity and possibly an increased metabolic efficiency in energy utilization contribute to the maintenance of energy balance. In adolescent girls suffering from anorexia nervosa RMR, either expressed in absolute values or per kg body weight or per kg FFM, was found to be significantly lower than in matched controls, which most

probably is an adaption to semi-starvation.[33,34] The results of BMR measurements in anorexia nervosa patients are similar to those in Keys' experiment mentioned before.

From several reviews on the effects of a negative energy balance it can be concluded that the BMR per kg body weight is not significantly reduced in moderate undernutrition. Only when the energy deficit is severe, i.e. much body weight has been lost, there is a measurable fall in BMR in absolute terms but also per kg body weight. This fall in BMR will be greater in lean than in obese subjects. [28,35-37]

In summary, it may be concluded that, although the limits are hard to define, in both animals and man severe energy restriction lowers RMR expressed in absolute terms. From studies performed in man it appears that the effect is greater in lean subjects than in the obese, due to a relatively greater loss of FFM. Loss of FFM should therefore be minimized. Long-term energy restriction, for example in undernourished labourers and in anorexia nervosa patients, decreases the activity of metabolic tissue and probably increases metabolic efficiency, since in these studies RMR expressed per kg FFM was also reduced. Decreased metabolic activity might be the result of decreased thyroid function or sympathetic nervous activity. The effect of energy restriction on the (neuro)endocrine balance will be discussed elsewhere in this manuscript.

EFFECTS OF AGEING AND ENERGY RESTRICTION ON FREE-RADICAL ACTIVITY: OXIDATIVE STRESS AND DNA DAMAGE

Oxidative stress

Free-radical reactions have been suggested to be responsible for the progressive accumulation of age-related degenerative changes and to a loss of functional capacity due to oxidative damage. This implies that reactive oxygen species, or free radicals, are produced incidentally and uncontrollably during aerobic metabolism. Once generated, free radicals initiate or promote the deleterious reactions that underlie the ageing process.

The suggestion by Sacher[13] that energy restriction reduces the metabolic rate, and by doing so, retards the ageing processes has been widely embraced. Indeed, Harman[38] linked this hypothesis to the 'free-radical theory of ageing'. His view was that by lowering the metabolic rate, the rate of electron transport in the respiratory chain will be lowered, leading to decreased production of free radicals and cell damage and thereby to a decreased ageing rate. The findings of Chipalkatti[39] that energy restriction in mice reduces the damage in tissues by free radicals support this hypothesis. Cutler[40] divided mammalian species into three separate categories according to their metabolic potential: averaged over their total life span most mammalian species expend about 220 kcal/g body weight, cat and non-human primates about 458 kcal/g, and man, capuchins and lemurs about 781 kcal/g. Within these

three categories the basal metabolic rate is apparently inversely related to species-specific life span, which supports the rate of living theory. According to Cutler ageing is partly due to free-radical-induced changes in the differentiated state of the cell. In his view, the optimal state of differentiation gradually degenerates into a state of 'dysdifferentiation' as a result of genomic damage by long-term exposure to free radicals. A higher rate of metabolism accelerates this process.

Another mechanism by which free radicals can modulate the ageing process has been postulated by Sohal and Allen.[41,42] They hypothesize that ageing is due to the loss of balance between prooxidants and antioxidants in cells, which is necessary for the maintenance of the differentiated state of cells. Whether ageing is due to increased levels of prooxidants (accumulation of free-radical damage) or to decreased antioxidative capacity remains unknown. Roa et al.[43] studied the effects of ageing and energy restriction on enzymes involved in free radical detoxification in rats. They observed that the activity and the mRNA levels of superoxide dismutase (SOD), catalase and glutathione peroxidase (GSH-Px) were diminished in older animals and that this decrease was eliminated by energy restriction. This indicates that the beneficial effect of an energy-restricted regimen is related to the maintenance of the free-radical scavenging capacity, which is controlled at the level of gene expression. These and other changes that occur in ageing but are prevented by energy restriction are summarized in Table 1.1. The data suggest that there is indeed a relationship between ageing and the activity of antioxidant enzymes as well as between ageing and lipid peroxidation. Generally speaking, in most studies mentioned, a decrease of the activity of antioxidant enzymes such as SOD, catalase and GSH-Px has been found while lipid oxidation increases. This indicates the involvement of peroxidative deterioration in the ageing process. Energy restriction, however, seems to improve protection against peroxidation in animals, which may result in the life-prolonging effect observed in animals.

As compared to younger people, in older people an increased plasma malondialdehyde content (a marker of overall lipid peroxidation),[44-46] decreased vitamin E level,[44,45] decreased vitamin C level[45] and decreased[44,45] or unchanged[46] GSH-Px activity have been observed in cross-sectional studies. From a longitudinal study[47] it appeared that those subjects who died during the study had a low SOD inducibility by paraquat (mean 2.4%) at the beginning of the study as compared to the survivors (mean 21%). These findings in human studies support the observations on free-radical damage and ageing in laboratory animals. Unfortunately, no human studies are available into the effects of ageing and energy restriction on antioxidants or oxidative stress.

DNA damage

Energy restriction reduces the incidence of spontaneous tumours and delays their appearance.[3,48] Besides lower levels of ingested dietary carcinogens, a decreased metabolic activity and increased detoxification of free radicals through ER could decrease the endogenous levels of DNA damage. Indeed, protection of DNA damage by ER has been observed in rat liver[49,50] and in the rat's mammary gland.[49] Moreover, enhancement of both specific activity and fidelity of DNA polymerases has been observed in energy-restricted mice.[51]

Damaged DNA is repaired in vivo by exonucleases and the resulting free water-solub
8-hydroxydeoxyguanosine (8OHdG) is excreted in the urine. Loft et al.[52] observed th
8OHdG excretion decreased with increasing Body Mass Index. The authors speculated th
this may relate to the fact that obese persons have a lower metabolic rate than lean one
As discussed before, obese people have a equal or even higher metabolic rate per kg FFP
than lean ones. The decreased 8OHdG excretion in the obese may therefore also be due
decreased DNA repair.

Energy intake and human cancer incidence has also been the subject
epidemiological studies. In a review by Weindruch[53] a number of studies are summarize
in which a relationship between high energy intake and the development of certain huma
cancers were reported, since a positive association between Body Mass Index or relativ
body weight and cancer has been demonstrated in most of these investigations. On the bas
of these studies and convincing evidence from studies in rodents he hypothesized that th
anticancer actions of ER, which are so evident in rodents, may also apply to man.

EFFECTS OF AGEING AND ENERGY RESTRICTION ON ENDOCRIN REGULATION MECHANISMS

Normal usage of neurons over a prolonged period of time may result in 'wear and tear
Ageing is accompanied by changes in hormonal secretion (blood hormone levels), hormon
responsiveness and neural activity. These changes in the neuroendocrine system have bee
related to specific ageing phenomena such as loss of bone mass, decrease in prote
turnover and in decline of reproductive capacity. Generally, ageing is characterized by a
apparent decrease in homeostatic capacity. Hormones can accelerate or inhibit the agein
process. Much of the ageing action of hormones comes from long-term studies of roden
subjected to hypophysectomy, thyroidectomy, ovariectomy or orchidectomy. Loss
hormones through surgical removal of these endocrine glands slows ageing in many tissu
and must (in)directly affect the rates of physiological ageing and development of age-relat
diseases. On the other hand, the evidence that hormones can produce anti-ageing effec
comes mainly from studies in older rats that demonstrate that hormone elevation (gonad
hormones, growth hormone (GH), somatomedins) can inhibit or reverse certain agein
changes.[54]

Changes in food intake and ER induce also a profound effect on hormonal and neur
activity. The life-prolonging effects of ER have been causally related to ER-induced effec
on the neuroendocrine system. ER generally results in decreased neuroendocrine functi
which might have a conserving effect.[55] Several excellent reviews have been written on th
effects of both ageing and ER on neuroendocrine activity. In this review we will brief

summarize the main systems involved and discuss especially the interactive effects of both ageing and ER.

There are several hormonal systems which can be modulated by ageing and/or energy restriction: 1) the sympathetic nervous system, 2) thyroid hormones, 3) anterior pituitary hormones and 4) hormones related to glucose homeostasis. In this chapter the effects of energy restriction on these systems will be described with, for each system, some introductory remarks on the changes with advancing age.

Ageing, energy restriction and the sympathetic nervous system

Stimulation of the sympathetic nervous system, with concurrent release of noradrenaline and adrenaline, increases the metabolic rate of many tissues and stimulates many organs of the body. In animals, urinary excretion of adrenaline and noradrenaline increases during ageing,[56] while cardiac catecholamine levels at rest and in response to acute exercise decline with age.[57] Human population studies indicate an increase in plasma catecholamine levels with advancing age.[58,59] This age-related increase in catecholamine concentration seems to be the consequence of an increased spill over into the plasma rather than a decreased clearance rate. In response to stress, the average plasma level increases to a greater extent in the elderly than in younger individuals. However, although the average levels of plasma adrenaline and noradrenaline during stress are greater in the elderly than in younger subjects, it is noteworthy that there is a substantial heterogeneity among elderly subjects. The age-related enhancement of catecholamine concentrations suggests that with advancing age a diminished responsiveness to β-adrenergic modulation seems to occur.[58,59] The underlying mechanism related to the age-related change in sympathetic nervous activity remains to be explained.

In Table 1.2 the main results of studies into energy restriction and the neuroendocrine system are summarized. Changes in urinary levels of catecholamines can be secondary to altered rates of synthesis, release, turnover and excretion, and to any combination of these. Underfeeding generally results in reductions in both noradrenaline release and clearance rates such that the decrease of the plasma concentration of noradrenaline is minimal.[60] However, a fall in plasma noradrenaline has been observed in obese human subjects undergoing therapeutic semi-starvation,[30,61] and diminished plasma noradrenaline levels are found in patients suffering from anorexia nervosa.[61] These results indicate that sympathetic nervous system activity is suppressed by energy restriction.

Thus, with advancing age the sympathetic nervous system seems to be affected but the precise mechanisms are unknown. Energy restriction results in decreased sympathetic function which in turn might be responsible for the observed lowered metabolic rate observed in energy-restricted subjects.

Ageing, energy restriction and thyroid hormones

The thyroid gland secretes two significant hormones, thyroxine (T4) an
3,5,3'-triiodothyronine (T3). Part of T4 is converted into T3. T3 is about four times ε
potent as T4, but is present in the blood in smaller quantities and persists for a shorter tim
than does T4. Both are very important in stimulating metabolic rate and thus play a
important role in energy balance. Thyroid secretion is controlled primarily by thyroic
stimulating hormone (TSH) secreted by the anterior pituitary gland.[62]

Thyroid failure is common among the elderly.[63] The natural history of thyroid failur
has been investigated in a four-year longitudinal study.[64] It has been found that elevate
TSH levels with normal T4 levels are common in otherwise healthy elderly subjects an
that progression to thyroid failure is common in such subjects. Those with greater elevatior
of TSH or with low to normal T4 values were more likely to progress to thyroid failur
than those with smaller elevations of TSH and those who did not have low to normal T
levels. The age-related decrease in T4 concentration might not be due to a decline of th
secretory function of the thyroid gland, but to an increase in metabolic clearance of T4.

In order to understand the effects of energy restriction on basal metabolic rate thyroi
hormone metabolism has been studied. Short-term animal studies (4-10 weeks) showed thε
energy restriction decreases T4 and T3 concentration but does not affect TSH level.[66,
Lower T3 and T4 levels, but no effect on TSH, could indicate a decreased responsivenes
of the hypothalamic-pituitary axis during underfeeding. Results from long-term animε
studies show no effect on T4 and TSH but the effects on T3 reported are conflicting: on
study noted a decrease[68] whereas another reported no effect on T3.[69]

In man the effect of energy restriction on thyroid hormones has also been studiec
Short-term very-low-caloric diets (VLCD) in obese people generally results in decreased T
levels and unaltered T4 and TSH levels.[20,21,69] Ten days of total energy deprivation i
normal-weight man showed early reductions and later increments of T3 and rT3 levels an
a slight and late decrease of T4. Besides these effects, a minute decrease in TSH has bee
seen.[70] These studies indicate that T3 plays an important role in the adaptation to conserv
energy stores during energy deprivation. In an epidemiological study Soares and Shetty
noticed that undernourished men had a lower BMR and a lower T3 level but similar T
levels as normally fed controls.

There are only a few studies that have looked at the effects of both ageing and energ
restriction on thyroid hormones. It has been noticed that in old ad libitum fed rats, but nc
in food-restricted rats, T4 levels were significantly lower than in young rats. Serum level
of T3 were unaffected by age or diet.[71] However, in another study energy restriction coul
not prevent the age-related fall of T4.[69]

In summary, animal and human studies suggest that ageing results in lower T4 level
possibly due to an increased clearance rate. This effect is probably attenuated by ER. Th

observed lower peripheral conversion of T4 into T3 in both man and animals contribute to a more efficient energy balance by lowering BMR per unit active tissue in th undernourished.

Ageing, energy restriction and pituitary hormones

Since the neuroendocrine system plays a critical role in body functions such a development, growth, metabolism and immune functions. During early and mature life i may have an equally important role in regulating the decline in body functions during late life.[72] Meites[55] observed three ageing events in the rat: 1) the decline in ability of th pituitary to secrete gonadotropic hormones, 2) the progressive increase in pituitary secretior of prolactin (PRL) and 3) the decline in secretion of growth hormone and somatomedir (insulin-like growth factor, IGF), and the resultant decrease in protein synthesis. These ageing phenomena have several features in common. One is that the principal cause fo their occurrence lies mainly in hypothalamic dysfunction. There seems to be evidence fo a decrease in release of gonadotropin releasing hormone (GnRH), the peptide that control: secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). The decrease of GnRH is probably caused by the decline in noradrenaline activity. Another commor feature is that these three ageing events appear during the first third to half of the rat's life span of about three years.[55] For example, the oestrous cycle in female rats becomes irregular when they are only 7-8 months old, and by 10-15 months of age they cease to cycle anc enter into a constant oestrous state without ovulation. In the ageing woman menopause generally occurs between 40 and 50 years of age.[73] However, caution should be exercisec before assuming that results of these animal studies can be extrapolated to man. The changes in pituitary hormones with ageing in man are summarized by Blackman.[74] In this review increases in both basal serum LH and FSH, but decreased testosterone levels are mentioned. Furthermore, variable responses of basal levels of PRL, GH and IGF to ageing have been reported.

Underfeeding has been reported to suppress the secretion of hypothalamic, pituitary and target gland hormones. Table 1.2, which summarizes results of several studies, shows that energy restriction leads to decreased serum levels of at least three anterior pituitary hormones (FSH, LH, PRL) in animals. Campbell et al.[75] injected their acutely starved (no food for 7 days) and chronically starved (no food for 7 days followed by ¼ of initial average for 2 weeks) rats with LH-releasing hormone (LHRH) and thyrotropin-releasing hormone (TRH). After this injection serum LH and TSH rose significantly in all groups of rats and FSH and PRL rose in the acutely, but not in the chronically, starved rats. These data suggest that the reduction in anterior pituitary hormone levels are due primarily to reduced hypothalamic stimulation rather than to the inability of the pituitary to secrete hormones.

In animal studies that studied both ageing and energy restriction an increase in serum prolactin with age was observed, but not in the restricted rats. Testosterone and LH levels decreased with age with higher levels in the energy-restricted rats.[69,71]

In 1986, Sapolsky[76] postulated his hypothesis about the neuro-endocrinological basis of ageing. His hypothesis was based on the notion that the neurons in the hippocampus, which have a high density of glucocorticoid receptors, are involved in the negative feedback regulation of glucocorticoid secretion and that stress-induced increases in plasma glucocorticoid concentration, which inevitably occur during the course of daily life, down-regulate these hippocampal glucocorticoid receptors. This may result in periods of hypercortisolism. With advancing age periods of glucocorticoidal excess causes degeneration of hippocampal neurons. Together, these effects form a feed-forward cascade of sustained hyperadrenocorticism. However, studies into ageing and the hypothalamic-pituitary-adrenal axis could not completely confirm Sapolsky's hypothesis. In aged Brown Norway rats an increased adrenocorticotropic hormone (ACTH) response to a conditioned stress stimulus was found but there was no impairment of the negative feedback action of glucocorticoids. However, the data supported the concept of an age-induced change in the balance of central corticoid receptor-mediated effects which consequently affects the set-point of homeostatic control and in turn, may progressively lead to a condition of age-related neuroendocrine disturbances.[77] On the basis of the 'glucocorticoid cascade hypothesis' it could be predicted that basal plasma corticosterone levels begin to elevate progressively on a given age. This prediction was not corroborated by the results of a longitudinal study of ad libitum fed male Fischer 344 rats.[78] Although an increase occurred between 9 and 13 and between 15 and 19 months of age, no further increase occurred between 19 and 25 months of age, while there was no increase with age in the food-restricted rats. The delay in recovery of plasma corticosterone levels upon stress was an important piece of evidence in the development of Sapolsky's hypothesis. In the same Fischer 344 rats it was found that the return of plasma corticosterone levels in ad libitum fed rats toward basal levels after a restraint stress is lower in rats 18-19 months old than in those 5-6 months old. However further slowing at 23-24 months, as would be expected on the basis of the 'glucocorticoid cascade hypothesis', was not observed. In addition, both food-restricted rats and ad-libitum fed rats of the same age exhibited similar time courses of recovery of plasma corticosterone levels upon stress. This study shows that the hypothesis that food restriction, at least in part, retards the ageing process by preventing the development of hyperadrenocorticism may be incorrect. Furthermore, the two studies described indicate that the 'glucocorticoid cascade hypothesis' does not describe a major aspect of the ageing process.

Ageing, energy restriction and hormones related to glucose haemostasis

Glucose and free fatty acids are the two main substrates for energy production and thus are regarded as the major metabolic fuel. Insulin and glucagon play an important role in the regulation of the fuel system. Insulin secretion is stimulated by elevated blood glucose levels. In skeletal muscle and in adipose tissue, insulin increases glucose transport, glucose oxidation, glycogen and protein synthesis, but inhibits proteolysis and lipoprotein lipase (LPL) activity. In the liver, insulin inhibits gluconeogenesis, and very-low-density lipoprotein secretion. Glucagon, a hormone that is secreted when the blood glucose concentration falls, has several functions which are diametrically opposed to those of insulin. Stimulated glycogenolysis and increased blood glucose concentration are the most important effects of glucagon.

One of the well-known features of ageing in both animal and man is the progressive development of impaired glucose tolerance. The precise mechanism is not known yet, but several reasons have been suggested for this deterioration. Amongst these are skeletal muscle insulin resistance,[79,80] impaired glucose oxidation in sensitivity to insulin stimulation,[81] decreased pancreatic insulin response to glucose stimulus,[82] and decreased response by the liver to the down-regulation by insulin on glucose output.[80] Results of a recently performed in-vitro study in the whole perfused pancreas and islets of Langerhans of Fischer 344 rats, indicate that glucose-stimulated insulin excretion is not significantly altered with age. However, it appeared that maintenance of insulin secretory capacity by ageing male rats is achieved by enhancement of β-cell sensitivity to glucose.[83]

Energy restriction influences glucose homeostasis. In rats maintained on a life-long restricted energy intake the progressive early peak of plasma glucose upon oral glucose loading, which occurs in ad libitum fed animals, does not occur. Nor did the energy-restricted animals show an increase in peak value with age, which was found in the ad libitum fed animals.[84] Low glucose and insulin concentrations have often been observed during periods of energy restriction.[59,85-87] The decrease in insulin levels in energy-restricted animals and man indicates that insulin is the primary signal responsible for fuel control during fasting in order to survive periods of energy restriction.[87] Reduced glucose levels might be another mechanism by which energy restriction can retard ageing since Cerami[88] advanced the hypothesis that glucose serves as a mediator of ageing. This hypothesis is based on the fact that non-enzymatic reactions occur between glucose and tissue protein, termed 'glycation of protein'. Lower glucose concentration and percentage glycosylation of haemoglobin were found in energy-restricted rats (60% of ad libitum)[89] but not in monkeys fed 70% of ad libitum.[90] These results suggest species-specific glucose metabolism and makes extrapolation to man difficult.

Table 1.2. Effect of energy restriction on the hormone system.

Hormone[a]		Effect	Subject	Period	Diet	Ref
Adrenaline	(pl)	=	non-obese men	10 days	400 kcal/day	60
	(pl)	=	non-obese women	7 days	15 kcal/kg bw/day	59

[a] (pl) = analysis in plasma; (u) = analysis in urine

In conclusion, ageing affects the hormonal system in both animals and man which manifested in dysfunction of the sympathetic nervous system, decreased T4 concentration decreased secretion of gonadotropic hormones, and decreased glucose tolerance. This ca be a result of 'wear and tear' with advancing age. Energy restriction also lowers th function of the neuroendocrine system by lowering noradrenaline and T3 in both anima and man and by lowering FSH, LH, and PRL levels which has only been studied in rat This confirms the hypothesis that ER may have a conservative effect. Moreover, the findir that ER prevents the decrease in T4, testosterone and LH provides more evidence for th hypothesis.

IMPLEMENTATION OF AN ENERGY RESTRICTED DIET

When comparing effects of energy restriction, which have been investigated in both anima and man, no obvious discrepancies have been found. From this point of view ER could hav a anti-ageing effect in man as well. However, looking at human studies on energy restrictic it is obvious that, except for Keys' semi-starvation study and some short-term starvatic studies, most (if not all) studies have been done in obese people. The diets that these obes received were mainly very-low-caloric diets (VLCD's). This is contradictory to the anim studies in which normal-weight animals were restricted to a less stringent low-caloric die Thus, to compare the outcomes of animal studies to studies in man it is necessary perform a study in which normal-weight people receive a moderately energy-restricted di while maintaining an adequate intake of essential nutrients. To which extent this energ supply should be restricted is open to discussion. However, this restriction should t achieved in such a way that it is acceptable to the subjects and does not lead deterioration of physical or mental performance capacity or to other health risks whe maintained over a longer period of time. Thus, the feasibility of moderate energy restrictic needs to be studied. It should also be investigated whether long-term moderate energ restriction leads to a new energy balance at a lower basal metabolic rate. A lower energ metabolism due to energy restriction would support Harman's hypothesis which is base on the metabolic rate and the generation of free radicals.

With regard to the onset of energy restriction Yu et al.[91] showed that energy restrictic started at early adult life was as effective in extending maximum life span of rats than whe it was started soon after weaning. This proves that energy restriction does not act t slowing growth and delaying development. Thus, it is not necessary to apply such a regime to children. The effects of starting at any later age than early adult life still needs to t investigated.

Of the three macronutrients present in food, fats provide the most convenient ar

concentrated source of energy, since 1 gram of fat provides approximately 37 kJ, whereas carbohydrates and proteins provide about 16 and 17 kJ/g respectively. In most affluent societies fat usually contributes 35 to 45% of total energy. Animal and human studies have shown that diet composition, particularly dietary fat intake, can significantly affect the amount of body fat.[92-96] In accordance with the growing evidence of a positive association between dietary fat and obesity, coronary diseases and cancer, nutrition experts are recommending that intake of fat be reduced to ca. 30% of total daily energy intake. The possibility of replacing fats in foods through the use of alternative ingredients has generated substantial interest among the food industry and nutrition professionals as well as among the lay public and news media.

The question that arises from our point of view is 'Does fat (and/or carbohydrate) substitution lead to energy restriction?'. In other words, is it possible to reduce one's energy intake through the consumption of fat (and sugar) substitutes? As an approach to study whether fat substitutes decrease energy intake, Lyle et al.[97] made use of historical dietary records. When fat-free foods were substituted in seven selected food categories (cottage cheese, cream cheese, sour cream, dressings for salads, frozen desserts, process cheese and commercial sweet baked foods), mean energy intake decreased by 460 kJ/day (ca. 6.2% of total energy intake). It should be noted here that in this study it was not known whether energy compensation would occur. Unfortunately, the existing published body of research literature, summarized by Mela,[98] does not directly and clearly answer this question. Most of the studies have been conducted in small patient populations within the confines of a laboratory or clinic or in free living healthy subjects given fixed meals or limited selections and have generally been of short duration. In most experiments in which free living subjects were offered foods covertly reduced in energy content, compensation for most or all the 'lost' energy occurred through increased consumption of these or other foods. With regard to fat substitutes in particular, the picture is less clear, but it would seem that (possibly not complete) energy compensation could be expected, accompanied perhaps by a moderate reduction in proportion of energy derived from fat.[98] Another number of studies confirm that a compensatory increase of fat reduction is very limited, i.e. that fat reduction has a beneficial effect on energy intake.[99-101] It is clear that there is a lack of consensus on whether fat substitutes will lead to energy restriction. Studies published on this subject have been carried out in relatively small groups and over a relatively short period of time. Therefore, long-term studies in large groups of consumers might provide more information on the compensatory behaviour in subjects consuming fat and/or sugar substitutes.

Besides the hypotheses on which this paper is based, there certainly are other theories about the routes by which energy restriction may retard ageing. There is still a big challenge in learning how energy restriction retards ageing but more importantly, although it will be hard to introduce it as an intervention, in finding out the relevance for man.

Outline of the thesis

The studies described in this thesis proceed from the phenomenon, described first by McCay et al.,[1] that restriction of the energy intake, while maintaining the intake of adequate amounts of essential nutrients, can retard ageing and extend life span in rodents. Moreover, diseases associated with ageing are retarded in their onset by energy restriction (ER). Initially, ER was started soon after weaning, but appeared also to be effective when introduced to adult animals.[2] Without question, ER is an important tool of the experimental gerontologist for studying the ageing process. However, little is known regarding its applicability as an intervention with respect to human ageing. Weindruch and Walford[3] state that they feel that this dietary regimen would be effective in humans, but they also discuss potential dangers and disadvantages. Stimulated by the ideas of Weindruch and Walford and their suggestions for a dietary regimen of 'undernutrition without malnutrition' the potential application of energy restriction in man has been studied.

In the first chapter the literature describing the effects of ER on three physiological processes related to ageing, i.e. adaptation of energy metabolism, free radical reactions and antioxidative capacity, and modulation of the endocrine system, have been summarized. From this review the following conclusions were drawn:
- In both animals and man severe energy restriction lowers the resting metabolic rate (RMR), expressed in absolute terms. Long-term energy restriction, for example in undernourished labourers and anorexia nervosa patients, decreases the activity of metabolic tissue and probably increases metabolic efficiency, since in these studies RMR expressed per kg fat-free mass was found to be reduced.
- In animals, a decrease in the activity of free radical scavenging enzymes with increasing age has been found. ER, however, seems to maintain and/or improve protection against free radical damage in these animals, which may play a role in the life-prolonging effect. Unfortunately, data on the effects of ageing and ER on damage due to free radicals or free radical scavenging capacity in man are absent.
- Ageing affects the hormonal system in both animals and man which is manifested in dysfunction of the sympathetic nervous system, decreased T4 concentrations, decreased secretion of gonadotropic hormones, and decreased glucose tolerance. This can be a result of 'wear and tear' with advancing age. ER prevents the decrease in

T4, testosterone and LH which provides evidence for the hypothesis that ER maintains the functional integrity of the neuroendocrine system.

Although there certainly are quantitative differences in metabolism between animals and man, the effects of ER, with regard to the three physiological processes mentioned in Chapter 1, described in both animals and man did not seem to differ between these species. Based on this knowledge one can argue that ER might have an anti-ageing effect in man as well. Therefore, there is a challenge in learning how ER retards ageing and in finding out the relevance for man. However, the life-long animal studies are hard if not impossible, to mimic in interventions with humans. Therefore, this project was started with a 10-week intervention study in order to investigate the applicability as well as potential health benefits or risks of a moderately energy restricted diet, aimed at 20% ER. The results of this study, performed in 24 healthy non-obese middle-aged men, are described in the next five chapters. In Chapter 3 the effects on 'general health' parameters such as lipid profile, blood pressure as well as physical and mental performance are presented. The effects on physical performance are further elaborated in Chapter 4. Chapter 5 describes to which extent energy metabolism and body composition are affected by the imposed level of energy restriction. The effects on fibrinolytic factors are reported in Chapter 6.

Since the beneficial effects of ER on the ageing process might proceed by lowering the production rate of free radicals (probably secondary to a lower metabolic rate) and/or by the maintenance of (or enhancing) effective scavenging capacity of free radicals the effects on the primary antioxidant defence system (antioxidant enzymes as well as antioxidant vitamins), oxidative damage and on markers of genotoxicity were also investigated in order to compare the effects of short-term ER in man with the effect observed in animals (Chapter 7).

This first study was performed under strictly dietary controlled conditions and does not provide information about the feasibility to reduce the energy intake under 'free living' conditions. Therefore, a second study was executed under 'free living conditions' in which the potential of reduced-fat products to reduce the energy intake was investigated. This study was part of a multi-centre study, the MSFAT-study (i.e. Multicentre Study on FAT reduction), on the health effects of consumption of reduced fat products. The control and reduced-fat products were provided through a realistic shop in order to mimic a 'free living' situation.

The design of this 6 month parallel comparison trial has been described extensively in Chapter 8. In the MSFAT-study the same parameters as in the first study were

measured. The effects on fibrinolysis and glucose tolerance are presented in Chapter 9. Since both energy restriction as well as dietary fat intake might affect the antioxidative capacity, again, parameters that reflect the antioxidant/prooxidant balance were measured, the results of which are reported in Chapter 10.

To summarize, the studies described in this thesis are performed in order to answer the following questions:
* What is the potential of implementation of an ER-diet tenable for the longer term?
  - what level of ER will be appropriate for the long term?
  - how can an ER-diet, acceptable for the long term, be achieved in man?
* Does ER result in health benefits and/or health risks?
* Does short-term ER affect the antioxidant/prooxidant balance, a potential underlying mechanism of the beneficial effects of ER, in man?

Finally, in Chapter 11 the results presented in these thesis are discussed in view of these questions.

ABSTRACT

Energy restriction (ER) retards the ageing process in animal models. It is possible that ER has a similar effect in humans. As a first approach to look after the potential application of ER in man the feasibility of a moderately energy-restricted diet was studied. 24 middle-aged non-obese men, selected from men responding to advertisements in regional newspapers, participated in the study. After a run-in period subjects were divided into two groups, a control group (n = 8) and an ER group (n = 16). Groups were matched on age and body mass index. The effects of 10 weeks of moderate ER (80% of habitual energy intake) on body composition, general health (blood pressure, lipid profile, routine clinical chemistry and haematology), physical and mental performance, and feelings of hunger, satiety and state of mind were measured. Subjects in the ER group lost about 7.4 ± 2.6 kg weight (P < 0.001). This weight loss concerned mainly loss of fat mass. Diastolic and systolic blood pressure decreased significantly within the ER group (P < 0.05 and P < 0.01 respectively). The increase in HDL-cholesterol level was significantly related to weight loss (P < 0.05). These results show beneficial effects of 10 weeks of moderate ER on blood pressure and lipid profile without adverse effects on physical and mental performance and feelings of hunger, satiety and mood.

INTRODUCTION

McCay et al.[1] were in 1935 the first to find that the restriction of energy intake, w adequate administration of essential nutrients, can retard ageing and extend life span in ra Since then, this finding has been confirmed and extended in a great variety of anim species such as rats, flies, mice and fish (for reviews see[2,3]). Moreover, it appeared tl energy restriction (ER) not only extends life span but also prevents or delays the onset many age-related diseases.[3]

Since ageing is a general biological phenomenon it is likely that energy restriction I similar effects in man. Most human studies on energy restriction deal with involunta situations of energy restriction and malnutrition of essential nutrients (e.g. war), with fasti or with very low caloric diets in obese men or women.[3-5] From these studies one canr conclude whether moderate energy restriction is beneficial for non-obese human beings. important aspect of extrapolating results of animal studies to the human situation is t uncertainty about the acceptability of long-term voluntary energy restriction by humans, well as the uncertainty about undesirable side effects.

It is hard, if not impossible, to simulate life-long animal studies on energy restricti in human studies. However, as a first approach at least two aspects can be studied in m 1) acceptability and feasibility; feelings of hunger and satiety, effects on general heal physical and mental performance and 2) comparison of the results of short-term ER in m with short- and long-term animal studies.

It is difficult to assess the level of energy restriction in man. In their semistarvati study, Keys et al.[6] showed that 50% ER led to decreased performance which is i acceptable for the long term. According to Apfelbaum,[7] it is likely that adult men can ad over time at a reduced body weight to about 7,537 kJ (1,800 kcal)/day, without continuc weight loss. Ross[8] observed in his animal studies that severe energy restriction at older leads to a decreased life expectancy. However, the lifespan of older rats could be extenc by a less severe regime of energy restriction. Thus, the age-dependend safe level of ener restriction in man can only be surmised.

Because of the anti-ageing effects of energy restriction and because of the lack knowledge about the effects of moderate energy restriction we performed an experimen which 24 non-obese healthy middle-aged men volunteered to use a moderately ener restricted diet (80% of habitual intake). As a first step to explore the applicability feasibility of moderate ER in humans, we assessed the effects on general health, physi and mental performance, feelings of hunger, satiety, and state of mind.

SUBJECTS AND METHODS

Subjects

Twenty-four apparently healthy middle-aged men (mean 42.9 yr; range 35-50 yr) selected from men responding to advertisements in regional newspapers, participated in this study. Subjects who had a normal body mass index (BMI) (mean 24.6; range 20.6-27.2), did not take medications, did not smoke, and drank less than four alcoholic drinks per day were included in the study. Each subject was medically screened by a physician. Routine clinical chemistry, ECG, blood pressure and lipid profile had to be within normal ranges. Subjects who reported to have an extremely high or low energy intake (< 9,300 and > 13,200 kJ/day) were excluded from the study. The study protocol was approved by the Institute's Medical Ethical Commitee and the participants signed an informed consent form. After completing the study the subjects received a suitable reimbursement.

Study design

Before the experiment started the participants' habitual energy intake was estimated by means of a 7-day dietary record method. Each participant was visited at home by a qualified dietitian, who presented and explained this method. The subjects were instructed to record all foods and drinks consumed and to continue their habitual lifestyle and consumption pattern. During these 7 record days the dietitian contacted them once by telephone to check whether there were any questions. After the 7-day period subjects were visited again by the dietitian to scrutinize the records so that questions as to quantity or vague descriptions could be resolved. Subjects were asked to weigh themselves every morning in underwear before breakfast and to record their weight to check for weight maintenance.

During the first two weeks of the experiment (run-in period) all subjects received a weight-maintaining test diet based upon the outcome of the 7-day dietary records. Since energy intake varied among individuals the subjects were divided into six 'energy groups' with different levels of energy intake, ranging from 9,304 to 13,147 kJ (stepwise increase by ca. 770 kJ). When subjects lost weight during this run-in period they were reassigned to a higher energy group.

After these two weeks the subjects were divided by lot into two groups: a control group (8 subjects) and an energy-restricted group (ER group; 16 subjects). These groups were matched on age and BMI. During the next 10 weeks the 8 control subjects were kept on their weight-maintaining diet, while the other 16 subjects received a test diet that contained 80% of the energy of their habitual (weight-maintaining) diet, and micronutrient levels approaching Recommended Dietary Allowances (RDAs). The 20% energy restriction was achieved by substituting low-fat margarine for margarine, light soft drink for soft drink, artificial sweetener for sugar, low-fat coffee cream for coffee cream, salad dressing for

mayonnaise, and skimmed yoghurt for whole yoghurt. In this way the intake of fat an carbohydrates was reduced while the intake of protein was maintained. This implied th the relative contribution of carbohydrates and fat to energy intake slightly reduced whi that of protein increased. An example of a weight-maintaining test diet and an energy restricted test diet is presented in Table 3.1.

The total experiment lasted 12 weeks. During the experiment the subjects visited th institute every evening to have dinner and to receive their food for the next 24 hours. Th subjects were not allowed to eat or drink anything but the food they received (exce water).

Measurements of weight, feelings of hunger and satiety and mood were recorded eve week before dinner. Mental performance was measured every other week before dinne Body composition, blood pressure and physical performance were measured at the end the run-in period and at the end of the experiment. At the end of the run-in period and the end of the experiment blood samples were taken for routine clinical chemistry, lip profile and haematology analysis. The study design is schematically presented in Figure 3.

Figure 3.1. Study design

Materials and Methods

Body composition. The subjects were weighed in underwear every week (Berke Ridderkerk, The Netherlands) before dinner. Body composition was computed fro measurements of body density using the hydrostatic weighing technique of Brozek et a Underwater weight was determined with a balance (Berkel, Ridderkerk, The Netherland and residual lung volumes were determined by helium dilution and a spirometer (Volute Mijnhardt, Bunnik, The Netherlands).

Blood pressure. Blood pressure was measured in supine position by means of oscillometric method using a digital blood pressure monitor (Omron, Tokyo, Japan) aft the subject had laid down for 15 minutes.

Table 3.1. Example of a weight-maintaining test diet and an energy restricted test diet.[a]

	Weight-maintaining	Energy Restricted
Breakfast	1 slice of brown bread **5 g margarine** 20 g cheese, full-cream	1 slice of brown bread **5 g low-fat margarine** 20 g cheese, full-cream
Lunch	3 slices of brown bread **15 g margarine** 2 slices of luncheon meat (30 g) 1 slice of saveloy (15 g) orange or apple	3 slices of brown bread **15 g low-fat margarine** 2 slices of luncheon meat (30 g) 1 slice of saveloy (15 g) orange or apple
Snacks	1 slice of Dutch honey cake 20 g cake **250 ml soft drink** 200 ml orange juice 2 cups of tea 3 cups of coffee **30 g sugar** **27 g coffee cream** ½ liter low-fat milk	1 slice of Dutch honey cake 20 g cake **250 ml soft drink, 'light'** 200 ml orange juice 2 cups of tea 3 cups of coffee **30 g artificial sweetener** **22.5 g low fat coffee cream** ½ liter low-fat milk
Dinner	100 g minced meat 100 g paprika sauce 125 g beans 125 g potatoes 75 g uncooked vegetables **15 g mayonnaise** **150 g whole yoghurt with fruit**	100 g minced meat 100 g paprika sauce 125 g beans 125 g potatoes 75 g uncooked vegetables **15 g salad dressing, 25% oil** **150 g skimmed yoghurt with fruit**
Total energy[b] Fat Carbohydrates Proteins	9,304 kJ 37% of total energy 51% of total energy 13% of total energy	7,511 kJ 37% of total energy 48% of total energy 17% of total energy

[a] Differences between the two groups are indicated in bold.
[b] Energy and macronutrient contents were calculated with the computerized Netherlands food composition table (UCV/NEVO).

Blood analysis. Blood was drawn from an antecubital vein after an overnight fast. Fo the analysis of lipid profile (triglycerides, total cholesterol, HDL-cholesterol, LDL cholesterol) commercially available kits were used (Boehringer Mannheim Diagnostica Amsterdam, The Netherlands; Hitachi 911, Japan). HDL-cholesterol was measured in the supernatant fraction after LDL-cholesterol precipitation. Routine clinical chemistry (urea creatinine, uric acid, total protein, ALAT, ASAT, GGT, albumin, alkaline phosphatase) was performed with a Hitachi 911, Japan (Boehringer Mannheim Diagnostica, Amsterdam, The Netherlands). Haemoglobin concentration and haematocrit were determined by using a semi automatic computer-equipped haematology analyser (Sysmex K1000, Japan; DA1000 Japan).

Physical performance. Physical performance was measured by means of an electromagnetically braked bicycle ergometer (HL-600R, Lode BV, Groningen, The Netherlands). The subjects were encouraged to keep on cycling until exhaustion while work load was increased every three minutes according to the supramaximal 12 min test described by Åstrand and Rodahl.[10] Maximum oxygen uptake ($\dot{V}O_2$-max) was measured using an Oxycon-4 (Mijnhardt, Bunnik, The Netherlands) in order to establish aerobic capacity. A blood sample for the determination of lactate was taken five minutes after cessation of the test (Boehringer Mannheim Diagnostica, Amsterdam, The Netherlands).

Hunger and satiety. For estimating the subjective hunger and satiety feelings, every week before dinner, five so-called visual-analogous scales were used. These scales consist of horizontal lines with a length of 15 cm, the left and right ends marked with the terms weak and strong. The subjects were asked to express their feelings at that moment about 1) having appetite for a meal, 2) having appetite for something sweet, 3) having appetite for a snack, 4) satiety and 5) faint with hunger, by making a vertical mark on the scale. The length between the left end of the scale and the vertical mark made by the subject served as the parameter used in the analysis.

State of mind (mood). The mood of the subjects was measured every week before dinner using a shortened Dutch version of the 'Profile of Mood States' questionnaire.[11] This questionnaire consists of 32 items measuring five dimensions: 'Depression', 'Anger' 'Fatigue', 'Vigor' and 'Tension'. For every item in the questionnaire the subjects had to mark to what extent the item was applicable to his feelings (not at all, a little, somewhat rather, very much).

Mental performance. For the measurement of mental performance a Taskomat test station was used (IZF-TNO, Soesterberg, The Netherlands[12]). The subjects had to perform a tracking task and a continuous memory task at the same moment. The task lasted 6½ minutes. The track was a sawtooth pattern moving upward on the screen. The subject controlled a little gate by means of a joystick and had to keep the gate centered on the line The distance between the center of the gate and the track was recorded at 32.6 s. intervals

The mean standard deviation of the distances of each run was used in the analysis. During the tracking task the continuous memory task was also performed. Every 2.7 s. a letter appeared above the gate of the tracking task. The subjects were instructed to react by pushing a button as soon as an A, B, C, or D (targets) appeared above the gate. The subjects were told to refrain from reacting when any other letter appeared. During this test run 107 letters appeared including 21 targets. The number of hits (a), correct rejections (d), false alarms (b) and misses (c) were recorded. From these data the accuracy of target detection or 'index of discrimination' was calculated, formulated as d' = $\ln((a*d)/(b*c))$.[13] To prevent undefined cases of d', data with a value equal to zero were reset to 0.5. This means that d' = 8.90 when no mistakes were made and d' = 8.17 when one mistake was made. For hits, reaction time was also recorded. Repeated performance on a test leads to an improvement of the score. To avoid bias introduced by a learning effect the subject had a pre-experiment practice during which both the tracking task and the continuous memory task were performed until a plateau value was reached.

Statistics

From most parameters (body weight, blood pressure, physical performance, lipid profile, haematology) data were collected at the beginning and at the end of the experimental period. Changes within groups were tested for significance with the paired Student's t-test, and differences in changes between the two groups were tested using the unpaired Student's t-test.

Since measurements of hunger and satiety, the profile of mood states, and mental performance were done repeatedly during the whole experiment, regression lines of the data for each subject were calculated. Differences in slopes of these regression lines between the two groups were tested with the unpaired Student's t-test.

Because all participants in this study lost weight during the experiment, Pearson's linear correlations were calculated between weight changes (as an indirect measure for the severity of ER) and changes in parameters analysed. These correlations are presented in Table 3.4.

BMDP statistical software was used to detect significantly different changes within and between the two groups, and to calculate correlations between parameters.

RESULTS

Body composition. Results for body composition, blood pressure and physical performance are presented in Table 3.2a. Both the control and the ER group lost weight. As expected, weight loss in in the ER group was substantial (Figure 3.2). Since weight loss is a

predictible result of energy restriction, this result shows that the subjects complied with ou
study. Weight loss and decrease in BMI in both groups appeared to be attributable almos
entirely to a loss of body fat.

   Blood pressure. Diastolic and systolic blood pressure decreased significantly durin
the experiment in the ER group. The decrease in blood pressure in the ER group was no
significantly greater than the nonsignificant decrease in the control group. Heart rate at res
did not change significantly in either group.

   Physical performance. During the maximal physical exercise test the control grou
reached a longer cycling time and a higher maximal power output after the experiment tha
before, whereas both parameters decreased within the ER group. Within the groups thes
changes were not significant (except cycling time in the control group). However, change
between the groups were significantly different. $\dot{V}O_2$-max decreased in the ER group, bu
did not change significantly in the control group. Ve-max, maximum pulmonary ventilatio
did not change during the experiment. Blood lactate concentration 5 minutes after cessatio
increased significantly in both groups and was similar in both groups.

* $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$ for changes within the group.

Blood analysis. As shown in Table 3.2b, HDL-cholesterol decreased significantly in the control group and showed a slight, nonsignificant tendency to increase in the ER group. The changes between both groups were significantly different. LDL-cholesterol level, HDL/LDL-cholesterol ratio and the HDL/total cholesterol ratio remained unchanged. The decrease in body weight was significantly related to increases in HDL-cholesterol (Figure 3.3). Haemoglobin concentrations decreased significantly and similarly in both groups. No significant changes have been observed on haematocrit. Routine clinical chemistry showed in both groups a decrease in the activity of the liver enzymes ALAT, ASAT, and GGT. Despite the stronger decreases in the ER group, the changes did not differ significantly between the two groups. Serum creatinine levels showed an increase in both groups but no differences between the groups could be observed. Uric acid decreased significantly in the ER group.

[a]   mean values and standard deviations of the control group and the energy-restricted group before (aft
a 2-week run-in period) and of the change after the experimental period are presented.
*   P < 0.05, **P < 0.01, ***P < 0.001 for changes within the group.

Hunger and satiety. Changes in feelings of hunger and satiety, state of mind an
mental performance are shown in Table 3.3. These changes are expressed as the mean slop
of the regression line of each parameter for each group during the experiment. Subjects i
the ER group showed decreasing scores on 'satiety' (i.e. feelings of satiety seemed t
decrease), but no significant differences in any parameter of the hunger and satiety scor
between the two groups were observed.

Mood. Slopes of the five states (depression, anger, fatigue, vigor and tension) of th
Profile of Mood States were all close to zero and showed no significant differences betwee
the two groups.

Mental performance. Data obtained from the measurements of mental performance (th
tracking task and the continuous memory task) did not show any differences between th
two groups.

Table 3.3. Mean slopes and standard deviations of scores on hunger and satiety, profile of mood states, and mental performance, obtained during the experiment.[a]

DISCUSSION

In this study we investigated the applicability and feasibility of moderate ER in man and looked after potential benefits and health risks of a moderately energy-restricted diet. We realize that a study like this has several limitations. First of all, the study lasted only 12 weeks, because in our opinion one cannot expect subjects to come to the institute every evening over a longer period of time. However, as no steady state was reached with respect to weight loss, it seems worthwhile to study the effects of moderate ER on general health on a longer term. Second, all the food subjects were allowed to eat was provided by the institute. So it was obvious to the subjects what to eat and thus how to eat restrictedly. It remains to be seen whether it is also possible to restrict energy intake under 'free-living' conditions. Since in this study short-term moderate ER did not affect physical and mental performance and feelings of hunger, satiety and mood, it should be feasible to restrict

energy intake even under 'free living' conditions, although one should keep in mind tha the subjects in this study were still losing weight when the study was terminated (Figure 3.2) and it was not clear when they would stabilize on a new, reduced weight Lastly, the food provided by the institute might, with regard to macronutrient and fatty acid composition and alcohol content, differ somewhat from the subjects' habitual diet. Changes in composition of the diet affect the lipid profile.[14,15] This might also have occurred during this study despite a run-in period of two weeks. During the whole experiment subjects abstained from alcohol. It is well known that this might lower liver enzymes such as ALAT ASAT and GGT. However, the decrease in GGT was significantly correlated with the relative decrease in body weight, indicating that energy restriction has a beneficial effec on liver function.

Weindruch and Walford[3] regard ER as an ethical option for human use, unde appropriate conditions. Others are less enthusiastic because of concerns about harmfu effects in children,[16] but animal studies have shown that ER starting at early adulthood wa as effective in extending maximum life span of rats as ER started soon after weaning.[8,17,1] As a first step, we studied therefore the applicability of moderate ER in middle-aged men A level of 20% ER was chosen. We regarded this a 'safe' level, well above the 50% EF reported by Keys et al.[6] which resulted in undernutrition and slightly above the 7.5 MJ/day level which, according to Apfelbaum,[7] is a level people can adapt to.

An accurate measurement of habitual food intake was the basis of this study. Both the dietitian and the volunteers were aware of the importance of the dietary record and were motivated to record as accurately as possible. Despite corrections made for weight loss during the 7 dietary record days and during the run-in period, subjects in the control group lost about 2.1 kg during the 10-week experimental period. This means that the energy intake recorded was below the energy expenditure. Assuming that 1 gram adipose tissue has an energy content of 29.7 kJ,[19] a loss of 2100 g body fat corresponds with a shortage o 62,370 kJ in 10 weeks, i.e. 891 kJ/day (ca. 8.5% of daily intake). We think that, in spite of all precautions taken, with the 7-day dietary record habitual energy intake wa underreported, a well known phenomenon in dietary studies. In an evaluation of 14 year of human dietary intervention studies Mertz et al.[20] reported an underestimation of habitua intake of 18%. One possible explanation is that underreporting is subconscious, motivated by the belief that maintaining a low body weight contributes to a good health and tha eating less will have beneficial effects. The same phenomenon might have occurred in ou study, to an extent varying from subject to subject. As a consequence, it looks plausible tha some subjects have restricted their diet for more than 20%.

In this study energy-restricted men lost about 7.4 kg weight. About 91% of this weigh loss appeared to be loss of body fat, measured by under-water weighing. Although result for body composition are dependent on the method used for assessment,[21] our result

indicate that almost no fat-free mass was lost as a consequence of moderate ER. Most other studies into ER and body composition have been performed in obese men or women given a very low- caloric diets (VLCD) over a certain period of time. In a review of 21 of such studies lasting from 2 up to 22 weeks, energy intake varied between 1,256 and 7,327 kJ/day resulting a in weight loss between 4.0 and 28.3 kg (mean 12.1 kg) and a in loss of fat-free mass between 1.1 and 7.2 kg (mean 3.5 kg).[22] This means that ca. 25% of the reduction in weight induced by VLCD is due to a loss of fat-free mass. Our study indicates that moderate ER is more beneficial, i.e. lean body mass is conserved at the expense of fat mass.

An ER-induced decrease in blood pressure has been found in obese[7,23] and in chronically undernourished labourers.[24] Fasting or ER is associated with a drop in plasma norepinephrine levels, diminished excretion of catecholamine metabolites and cardiovascular signs of diminished sympathetic activity.[25,26] In this study blood pressure decreased significantly in the ER group which is in agreement with the observed suppressed sympathetic activity. However, the decrease in blood pressure in the ER group did not differ significantly from that in the control group. Across all volunteers the decrease in either systolic or diastolic blood pressure did not correlate significantly with decrease in body weight. From this study and the studies mentioned one could conclude that a more pronounced effect on blood pressure only occurs at a diet more restricted than we applied.

The fact that moderate ER did not affect total cholesterol and LDL-cholesterol levels confirms to some extent the findings of Wood et al.[27] who studied the effects of a one-year prudent weight-reducing diet in men with overweight. Regular dietary recommendations in group sessions extending over one year resulted in a decrease in energy intake by 27%, a decreased (saturated) fat intake and a mean weight loss of 5.1 kg. After this year no significant changes were found in plasma total cholesterol, LDL-cholesterol and HDL-cholesterol levels. As shown in Figure 3.3 and Table 3.4, the increase in HDL-cholesterol in our study correlated significantly with the decrease in body weight. A recently published meta-analysis[28] led to the conclusion that weight reduction is inversely related to changes in total cholesterol, triglycerides and LDL-cholesterol. A reduced stabilized weight is associated with higher HDL-cholesterol levels, whereas in subjects actively losing weight lower HDL-cholesterol levels are observed. Since 'obesity' and 'diet-reducing' were key words used in the literature search for this meta-analysis it is very likely that most of the studies found deal with very low-caloric diets. In contrast with our study, these diets have a macronutrient composition widely diverging from the habitual diet. Besides weight reduction, diet composition plays an important role in plasma lipid profile[14,15] and may explain different outcomes on lipid profile in weight reduction studies.

After the experimental period subjects were encouraged to cycle at least as long as th
first time. The energy required for physical performance is, of course, derived from the foo
eaten, and therefore the capacity of an organism to accomplish physical work will ultimatel
decrease with continued undernourishment. Decreased physical performance has bee
observed after starvation[29] and after 50% ER for a longer period of time.[6,30] Subjects in th
control group showed a significantly longer cycling time (CT) and thus had a highe
maximal power output after the experimental period than the subjects in the ER group
There were no differences between the two groups in other parameters measured such a
maximum oxygen uptake ($\dot{V}O_2$-max), maximum heart rate, and maximum ventilator
capacity ($\dot{V}e$-max). None of the changes in variables measured during these maxima
exercise tests correlated significantly with weight change, indicating that 10 weeks o
moderate ER does not lead to a decreased physical performance. A maximum performanc
capacity test of any type always includes a motivation or cooperation factor. To obtain th
best possible score, the individual must be willing to push himself to the limit and t
continue work until the last possible second of endurance. Thus the motivation factor play

46

an extremely important role in physical performance. It therefore cannot be excluded that subjects in the ER group stopped cycling earlier because of their 'belief' that it was impossible to perform better because of their ER.

Scores on feelings of hunger and satiety showed a large standard deviation. Energy-restricted subjects noted a decrease in satiety feelings and an increase in 'faint with hunger', which might be expected. However, the large standard deviation might explain why we failed to find any differences between groups.

Slopes with regard to the Profile of Mood States were all close to zero indicating that the five dimensions recorded only changed slightly during the experiment. Again, a large standard deviation might have precluded significant differences between the two groups.

Table 3.4. Linear correlations of parameter changes with absolute and relative weight changes (n=24).[1]

	Δ weight (absolute)	Δ weight (relative)
Δ body mass index	0.933*	0.932*

β_1 tracking error	-0.248	-0.143
β_1 accuracy d'	-0.077	-0.077

[1] Only parametes showing significant changes within or between groups are listed.
* P < 0.05.

With regard to mental performance no differences between the control and experiment
group were observed on the Taskomat test station, nor did the subjects complain abou
being less concentrated. In the Minnesota experiment by Keys et al.[6] in which 23 men wei
subjected to semi-starvation, subjects complained about inability to concentrate, difficul
in developing thoughts, and declining general alertness and comprehension. However, th
measured intellectual performance did not change. It should be noted here that the facto
of learning may have been a complication in Keys' study. In our study, to minimize th
learning effect, all volunteers were trained on the test station several times before th
experiment started.

The results presented here indicate that moderate ER might be a feasible interventic
in terms of health risks and satiety. However, long term effects need further investigation

Another relevant question, not adressed to in this report, is whether ER in man wi
have similar anti-ageing effects as in animals. Although the mechanism through which E
modulates the ageing process is unknown the (short term) changes in man induced by E
can be compared with short term effects in animals. Some provisional data of ER on th
oxidative stress and the neuro-endocrine system will be reported elsewhere and are subje
for further investigation.

In conclusion, 10 weeks of moderate ER leads to a significant weight loss which is main
due to a loss of fat mass. Further, this study showed that 10 weeks of moderate ER hav
significant beneficial effects on blood pressure and HDL-cholesterol levels without havin
adverse effects on physical and mental performance, and feelings of hunger, satiety an
mood.

In future research we will attempt to obviate most of the difficulties of a controlle
study by studying the feasibility of a longer-term moderate energy restriction in subjects i
'free-living' conditions.

Effects of moderate energy restriction on physical performance and substrate utilization in non-obese men

Erica J.M. Velthuis-te Wierik, Ludowieka V. Hoogzaad, Henk van den Berg and Gertjan Schaafsma

TNO Nutrition and Food Research Institute, Zeist, The Netherlands

ABSTRACT

Energy restriction (ER) has shown to be an effective 'anti-ageing' factor in rodents, resulting in an increased life span and preventing or delaying the occurrence of many age-related diseases in rodents. As a part of a feasibility study on the potential application of ER in humans, we studied the effects of moderate ER on physical performance in 24 apparently healthy, non-obese middle-aged men. After two weeks of weight maintenance the ER group (n = 16) received 80% of their habitual energy intake, while a control group (n = 8) still received their weight-maintaining diet for ten weeks. Physical performance (bicycle ergometer) was estimated by a maximal (until exhaustion) and a submaximal (30 min at 60% of $\dot{V}O_2$-max) exercise test. After the experimental period the subjects in the ER group had a significantly shorter cycling time (Δ = 1.31 ± 1.14 vs. –0.45 ± 1.56 min, P = 0.01), and thus had a lower maximal power output (Δ = 4.3 ± 5.9 vs. –6.3 ± 13.6 Watt, P < 0.05) and maximal oxygen uptake (Δ = 0.03 ± 0.18 vs. –0.18 ± 0.32 l/min, P = 0.05) during the maximal exercise test, than the subjects in the control group. None of these changes correlated with weight loss. As in every exercise test, motivation could have played an important role. During the submaximal exercise test no significant changes between the two groups in HR, $\dot{V}O_2$, RER, and FFA, glucose, lactate and catecholamine levels were observed. It is concluded that 10 weeks of moderate ER lead to a slight but significant decrease in maximal power output, which is not related to weight loss. Moreover, no changes on submaximal physical performance and on substrate metabolism have been observed although significant alterations in body weight (–7.4 ± 2.6 kg) occurred.

INTRODUCTION

Already in 1934, McCay and Crowell[1] reported that restriction of the food intake in rat
markedly increased longevity. Since then, numerous studies have verified the life-prolonging
effect of energy restriction (ER) in various strains of animal species.[2-5] In addition, ER ha
been observed to inhibit the development of age-related diseases, such as atherosclerosis
cardiovascular disease and various cancers.[6] Although the underlying mechanism(s) of th
'anti-ageing' effect has not yet been unravelled, the effect on the antioxidant and fre
radical scavenging capacity, the neuroendocrine system, as well as on gene expression, hav
all been causally related.[7,8]

However, during periods of severely restricted food intake the capacity for physica
performance might decrease as has been observed in the semistarvation experiment of Key
et al.[9] Decreased physical performance capacity would be an undesirable effect that migh
complicate the applicability of moderate ER in man and should hence be prevented
Moreover, dieting is generally practiced in sports, also lean people, which might affec
performance.

Only few studies have dealt with energy restriction and physical performance. Th
subject focused on is either 25 days and 26 weeks of semistarvation (i.e. 50% ER),[9,1]
chronic undernutrition in children[11] or 3.5, 5 and 1 day of fasting.[12-14] To our knowledge
no earlier studies were reported on the effects of moderate ER on physical performance i
the nonobese human. Therefore, as a part of the study into the feasibility of moderat
energy restriction in man, we studied the effects of a 10-week 20% ER diet on physica
performance parameters. Moreover, to assess metabolic adaptation during moderate energ
restriction, substrate utilization during submaximal exercise was studied.

MATERIALS AND METHODS

Subjects
Twenty-four apparently healthy men, aged 34-51, were selected from respondents t
advertisements in regional newspapers to participate in this study which lasted 12 weeks
All subjects were nonsmoking, nonobese men (Body mass index < 27 kg/m²), and showe
a normal routine clinical chemistry. Each subject was medically screened for the require
test protocol on the basis of a health questionnaire and a medical examination whic
included blood pressure and electrocardiographic measurements. None of the subject
participated in regular sports or fitness programs for more than 4 hr/week.

The study was reviewed and approved by the Medical Ethical Committee of the TN(
Toxicology and Nutrition Institute, and the subjects were provided detailed informatio

about the test procedures before giving their written consent to participate.

Experimental design

Before the experiment started the habitual energy intake of the subjects was estimated by means of a 7-day dietary record. During the first two weeks of the study (run-in period) all subjects received a weight-maintaining test diet that contained the same amount (± 0.6 MJ/day) of energy as reported in their 7-day dietary record (range: 9.3-13.2 MJ/day).

After this run-in period, the subjects were divided into a control group (n = 8) and an energy-restricted group (ER group, n = 16). These groups were matched for age, height and initial weight (Table 1). The assignment to groups was done randomly. During the next 10 weeks the ER group consumed a restricted test diet, providing 80.0 ± 5.1% of the energy of their test diet, while the control group continued their test diet. The 20% energy reduction was achieved by substituting low-fat and artificially sweetened products for ordinary products. The diets were composed such that the relative contribution of the carbohydrates, fat and protein to total energy intake was 51%, 34% and 15% and 47%, 36% and 17% in the control group and the ER group respectively. More details on the experimental protocol and the diets are described elsewhere (Chapter 3).

All food was provided by the Institute. The subjects consumed their dinner at the Institute every evening and then received food for the next 24 hours. The subjects were not allowed to eat or drink anything but the food supplied. Water could be taken ad libitum. Since subjects in the ER group were expected to loose weight, compliance was controlled for as much as possible by weighing the subjects every week, and by a daily questionnaire.

All subjects performed a maximal and a submaximal bicycle ergometer test during the run-in period and at the end of the intervention period, using exactly the same protocol. The submaximal exercise test was performed two weeks after the maximal exercise test. The subjects were not allowed to eat, drink coffee or to engage themselves in physical activity for a period of 2 hours prior to any exercise test in order to standardize the procedure and to avoid gastrointestinal complaints. All subjects were tested during the afternoon in the same order in any exercise test.

Body composition

Subjects were weighed every week in underwear to the nearest 0.1 kg, before having dinner at the Institute (Berkel, ED-60-T, Ridderkerk, The Netherlands). Body composition was determined from measurements of body density using a hydrostatic weighing technique of Brozek et al.[15] Underwater weight was determined to the nearest 0.1 kg by a balance (Berkel, SK, Ridderkerk, The Netherlands) while simultaneously the residual lung volume was determined by helium dilution and a spirometer (Volutest, Mijnhardt, Bunnik, The Netherlands).

Exercise tests

The subjects had to perform exercise tests on an electromagnetically braked bicyc[le] ergometer (Lode, model L-77, Groningen, The Netherlands). During exercise, ventilato[ry] and gas exchange parameters were monitored and printed every 30 s by an open-circ[uit] sampling system (Oxycon-4, Mijnhardt, Bunnik, The Netherlands). O_2 and CO_2 analyse[rs] were calibrated against standardized gas mixtures prior to testing. The subjects breath[ed] through a low-resistance breathing valve (Hans Rudolph #2700, Kansas City, MO). Hea[rt] rate was monitored electrographically throughout the test (Transport Monitor, Lamé[ris] Medical Equipment, Groenekan, The Netherlands).

Maximal exercise test

The method used to obtain maximal oxygen uptake ($\dot{V}O_2$-max) was derived from t[he] supramaximal 12 min test described by Åstrand and Rodahl.[16] After warming up with a [3] min load at 100 Watts, $\dot{V}O_2$-max was predicted according to the heart rate at the end of t[he] second minute, using the nomogram of Åstrand.[16] This predicted $\dot{V}O_2$-max was th[en] corrected for age and a matching work load of 80% was calculated. This was the work lo[ad] for the next 3 minutes, followed by a 3 min load at 115% and a 3 min load at 120[%] $\dot{V}O_2$-max, until exhaustion. The subjects maintained a constant pedalling rate at 60 rp[m] throughout the test as indicated by a metronome.

Exhaustion was defined as the point in each test at which the pedalling rate could n[o] longer be maintained, despite the subjects being encouraged to continue as long as possibl[e]. Criteria for maximal effort were no further increase in oxygen uptake ($\dot{V}O_2$) despite a[n] increase in work load and either 1) blood lactate concentrations greater than 10 mmol/l, 2) [a] respiratory exchange ratio (RER) above 1.10, or 3) a heart rate greater than 220 min[us] age.[16,17] The subject's maximal produced power output (Po-max) was defined as the highe[st] work load which could be achieved.

In the maximal exercise test as performed in this study, a contribution of anaerob[ic] energy to total power output is likely.[16] The power/oxygen consumption ratio (P/$\dot{V}O_2$) ca[n] offer an impression of the relative contribution of anaerobic energy to total power outp[ut]. In this ratio $\dot{V}O_2$-max is expressed in Watts, by assuming that only glycogen is oxidized a[nd] that each liter of O_2 is equivalent with 21.2 kJ of energy. The P/$\dot{V}O_2$ ratio will increase [at] a higher relative contribution from anaerobic sources.[18,19]

Submaximal exercise test

The submaximal work loads were chosen such that they represented 60% of the individual[s'] $\dot{V}O_2$-max. Before blood sampling for assessment of basal (t = 0) catecholamine level[s] subjects rested for 15 min in supine position. The exercise period was 30 min and t[he] subjects had to maintain a pedalling rate of 60 rpm.

The rate of energy input (Pi), expressed in Watts was calculated from the oxygen uptake (l/min) using formula 1:

$$Pi = \frac{(4.940 \text{ RER} + 16.040) * \dot{V}O_2}{60} \qquad \text{(eq 1)}$$

where RER equals the respiratory exchange ratio.[20] Pi was calculated for the period from 5 to 10 min and for the period from 25 to 30 min after the beginning of the test, assuming that after 5 min of exercise oxygen uptake reaches a 'steady state'.[16] The resulting values were averaged over the 5 min period.

Blood sampling

Blood samples were drawn fiom a catheter inserted in an antecubital vein. Blood samples for the analysis of lactate were taken 5 min after cessation of the maximal exercise test. During the submaximal test blood was drawn 15 min before the test (t = –15), at the start of the test after 15 min of resting in supine position (t = 0), after 10, 20 and 30 minutes of cycling (t = 10, t = 20 and t = 30), and 5 and 15 minutes after the test (t = 35 and t = 45) for the analysis of lactate. At t = 0 and t = 30 blood was also drawn for the analysis of glucose, free fatty acids and catecholamine levels.

Lactate, glucose and free fatty acids were analysed using commercially available kits (Boehringer Mannheim Diagnostica, Amsterdam, The Netherlands; Hitachi 911, Japan). The catecholamines norepinephrine, epinephrine and dopamine were determined radioenzymatically as described by Peuter and Johnson.[21]

Statistics

All values in the tables are expressed as mean ± SD and $\dot{V}O_2$ is expressed as STPD value. BMDP statistical software was used to perform Student's t-tests to establish differences between and within groups. Probabilities of difference less than 0.05 were regarded as statistically significant. To establish changes within groups paired t-tests were performed. Comparison of the changes of the two groups were made in unpaired t-tests. Skewed frequency distributions were transformed logarithmically before t-test. Analysis of variance with repeated measurements was used for the lactate data. Because all participants lost weight during the experiment Pearson's linear correlations were calculated between weight loss (as an indirect measure for the severity of ER) and changes in parameters analysed.

RESULTS

Body composition

Mean values of body weight (BW), lean body mass (LBM) and body fat (BF) are presente
in Table 4.1. Both BW and BF were significantly reduced in both groups after th
experiment and, as expected, these losses were greater in the ER group (P < 0.001), wherea
LBM remained unaltered. This indicates that the loss of body weight was mainly due to
loss of body fat rather than lean body mass.

Maximal exercise test

Table 4.2 summarizes average values before the intervention and the change observed aft
the study for maximal heart rate (HR-max), maximal power output (Po-max), maxim
oxygen uptake ($\dot{V}O_2$-max), $\dot{V}O_2$-max expressed per unit of LBM, highest respirato
exchange ratio (RER-max), maximal pulmonary ventilation ($\dot{V}e$-max), time until exhaustic
(ET) and blood lactate concentration 5 min after cessation. The power/oxygen consumptio
ratio (P/$\dot{V}O_2$) was calculated from Po-max and $\dot{V}O_2$-max. None of the parameters we
different between the two groups at the start of the intervention.

After the intervention period of 10 weeks the ER group reached significantly low
Po-max and a shorter ET than the control group. $\dot{V}O_2$-max (either expressed in absolu
terms or per kg LBM) decreased significantly in the ER group, but these decreases we
not significantly different from the changes in the control group. The change in P/$\dot{V}O_2$ rat
tended to be higher in the ER group than in the control group. Lactate levels increas
significantly in both groups, and this increase tended to be higher in the control group.

As weight loss might be an indirect measure for the severity of ER, the changes in parameters measured during this maximal exercise test were correlated with changes in body weight. However, no significant correlations were found.

Submaximal exercise test

Table 4.3 summarizes the results of the submaximal exercise test. RER between t = 25 and t = 30 increased in the ER group, which might be due to a lower starting value. Energy input (Pi), calculated according to formula 1, decreased significantly in the ER group, and this decrease correlated significantly with weight loss. No effects on FFA, glucose, catecholamine and lactate levels (Figure 4.1) were found.

DISCUSSION

Effects of moderate energy restriction; general findings

In the present study BW was significantly reduced in both groups but, as expected, weight loss in the ER group was substantial (–7.4 ± 2.6 kg). The fact that subjects in the control group lost weight during the experiment is characteristic of the problems that are encountered when feeding a weight-maintaining test diet. Underreporting is very common in human dietary intervention studies and most probably has also occurred in this study.

Figure 4.1. Mean lactate concentrations during submaximal exercise. Data points are mean ± SD.

This implies that the ER group might be restricted by more than 20% because underreporting may have occurred in this group as well. Results of the measurements of BF and LBM by underwater weighing before and after the diet indicate that the decrease in BW was almost entirely due to a significant BF loss rather than to a loss of LBM. It has been observed in studies dealing with very low caloric diets that about 25% of the weight loss was due to loss of fat-free mass,[22] moderate energy restriction might preserve this loss of fat-free mass. This conservation of fat-free mass might play a role in the minimizing the decrease in physical performance during moderate energy restriction.

Effect of moderate energy restriction on physical performance
Physical performance decreases after 26 weeks of semistarvation,[9,10] whereas impairments after a few days fast are minimal.[12,14] The major question in the present study was whether or not a regimen of moderate ER affects physiological parameters during maximal and submaximal exercise.

No significant changes in Ve-max were found as a result of the dietary intervention.

$\dot{V}O_2$-max expressed as an absolute value (i.e. l/min) allows assessment of the effect
dietary manipulation on the capacity of uptake, transport and utilization of O_2 to
assessed.[23] This parameter decreased significantly in the ER group and this fall near
reached significance when compared to the change in the control group. However, $\dot{V}O_2$-ma
expressed per unit LBM decreased in the ER group but this change was not significant
different from the control group. Subjects in the ER group showed a shorter time un
exhaustion (ET) after the intervention and therefore had a decreased maximal powe
$\dot{V}O_2$-max and maximal heart rate since these changes were significantly related. Th
decrease in maximal power output in the ER group is minor, but significantly different fro
the slight increase in the control group. The individual's ability to sustain progressi
incremental exercise of the type we used is highly dependent on the glycogen content
the muscles which, in turn, is dependent on the type of diet before exercise.[24] When musc
glycogen is markedly reduced by prior exercise, by consumption of a diet rich in fat ar
protein[26] or by fasting,[13,27] aerobic metabolism becomes more dependent on the oxidati
of fat. A short-term very-low-caloric diet (VLCD) in obese subjects did not affect physic
performance,[23] or alter muscle glycogen, lactate, pyruvate or energy stores.[8] Althou;
muscle glycogen concentrations were not measured in this study (i.e. no muscle biopsi
were taken), a reduction of the muscle glycogen stores by the 20% ER diet seems unlikel
as no significant changes in RER-max were noted and no decreased lactate values we
found.[25] Blood lactate concentration is widely accepted as an indicator of anaerob
glycolytic metabolism.[24] Lactate levels 5 minutes after exhaustion increased significant
and similarly in both groups. The $P/\dot{V}O_2$ ratio can offer also an impression of the anaerob
contribution to total power output. This variable was not affected after the interventi
period, suggesting no change in anaerobic metabolism. Thus, lower glycogen levels and
lower anaerobic contribution most likely do not account for the decreased cycling time.
maximum performance test of any type is always biased by a motivation or cooperatic
factor: in order to obtain the best possible score, the individual must be willing to pu
himself to the limit and to continue work until the last possible second of exhaustion. In a
practical work situations the motivation factor is extremely important in physic
performance. After the intervention period subjects were encouraged to cycle at least
long as the first time. It is possible that subjects in the ER group did not cycle long
because of their supposed reduced power, as a consequence of their negative energ
balance. Alternatively, it is possible that ER reduces more directly the motivation
physical strain.

To assess whether a relationship between weight loss and the physiological indic
measured could be demonstrated, linear correlations between weight changes (as an indire
measure of energy restriction) and changes in several parameters were calculated for t
whole group (n = 24). None of the changes in variables measured during these maxim

exercise tests correlated significantly with weight change. From this finding we conclude that 10 weeks of moderate ER lead to a slight but significant decrease in maximal power output, which is not related to the amount of weight loss.

Effect of moderate energy restriction on substrate utilization

Moderate restriction of the energy intake did not affect substrate utilization (Table 4.3). Previous studies on the combined effects of fasting and moderately intense exercise have shown increased reliance on fats and decreased utilization of carbohydrates as inferred from changes in plasma free fatty acid (FFA) concentrations and RER.[14,27-30] In all these studies fasting resulted in significantly higher FFA values, indicating a greater fat mobilization and utilization. This was also evidenced by RER values near 0.70 during the first 30 min of exercising on a treadmill at 70% $\dot{V}O_2$-max.[29] Thus, after fasting fatty acids are the most obvious energy substrate. From our data no change in substrate utilization during submaximal exercise was apparent as a result of 10 weeks of moderate energy restriction. However, our study differs in some aspects from the studies mentioned before. First, in contradiction to these fasting studies, in the present study subjects were restricted in their energy uptake for only 20%. Second, since both artificial sweeteners and low fat products were used, the relative contribution of the macronutrients to total energy intake did not change during the experiment. Therefore, the diet might replenish glycogen stores sufficiently, which is also indicated by unaltered lactate levels. So, despite substantial weight loss substrate utilization remains unaltered during submaximal exercise. The increase in RER levels observed in the ER group might be caused by lower starting values. These lower starting values are most likely explained by differences in physical activity. At the time of the submaximal exercise test all subjects used standardized meals with similar macronutrient composition.

When an individual is fasting the body attempts to preserve the limited carbohydrate stores. One method to accomplish this is by reducing sympathetic nervous system (SNS) activity. Reductions in norepinephrine turnover have been reported to occur with fasting in an attempt to reduce individuals' resting metabolic rate, thereby sparing fuel utilization.[31] Another function of catecholamines is the regulation of muscle glycogenolysis. Epinephrine binds to β-adrenergic receptors on the skeletal membrane, initiating a cascade of events leading to glycogen breakdown which ultimately increases lactate production. Decreased epinephrine, norepinephrine and lactate levels during exercise were found after glycogen depletion.[32] The fact that there were no differences between both groups in plasma catecholamine and lactate levels during submaximal exercise indicates that moderate energy restriction did not change SNS activity despite substantial weight loss.

Power input (i.e. energy expenditure) as calculated from the formula by Garby and Astrup[20] decreased significantly in the ER group although power output did not change.

Since there are no decreased RER values the decrease in power input must be attributed t
the decreased O_2 consumption ($\dot{V}O_2$). Decreased oxygen consumption during rest an
exercise has also been observed in obese women on a very-low-caloric-diet.[33] Th
explanation might be that the subjects showed a decreased metabolic rate (Chapter 5). Th
decrease in power input at t = 5 up to t = 10 correlates significantly with the decrease i
body weight (r = 0.454; P < 0.05).

To summarize, it is concluded that 10 weeks of moderate energy restriction decrease
maximal power output in non-obese middle-aged men. However, this decrease was no
related to a decreased body weight. Despite a substantial weight loss, no effect on plasm
FFA, glucose, catecholamine and lactate levels was observed, indicating that substrat
utilization remained unchanged. Further, during submaximal exercise moderate energy
restriction led to lower power input (energy expenditure) while power output did no
change, indicating a decreased resting metabolic rate.

The duration and degree of ER and the intensity and duration of the exercise perio
seem to be important factors determining changes in physiological performance parameters
This study lasted only 12 weeks, since we expected that this was the maximal period fo
subjects to visit the institute every evening. However, since no steady state was reache
with respect to weight loss, it cannot be inferred from this study whether significan
alterations in physical performance and metabolic adaptation will occur beyond 10 weeks
Therefore, it seems worthwhile to study the effects of moderate ER on a longer term. Thus
the long-term effect of ER diets as well as the minimum energy intake necessary to preven
physiological changes deserve further investigation.

Impact of a moderately energy-restricted diet on energy metabolism and body composition in non-obese men

ABSTRACT

Since little information is available on the capacity of the non-obese to adapt to a moderate decrease in energy intake, the effect of a 10-week moderately energy-restricted diet (ER) on energy expenditure and body composition was studied in a controlled intervention study. After a weight-maintaining run-in period of 2 weeks, the ER group received a diet that contained 9.2 MJ/day on average, i.e. 80% of the energy of their habitual diet (estimated by means of a 7-day dietary record) for the next ten weeks while the control group received the weight-maintaining diet. 24 healthy non-obese, middle-aged men participated. They continued daily life habits and came to the Institute every evening to have dinner and to receive food for the next 24 hours. Subjects were matched for age and body mass index and randomly assigned to a control group (n = 8) or an ER group (n = 16). Average daily metabolic rate (ADMR, i.e. total energy expenditure), measured with doubly labeled water in 8 subjects of the ER group, appeared to be 82.5% of reported energy intake resulting in an actual level of energy restriction in these eight subjects of 33% on average (range 18-42%), rather than 20%. Subjects in the ER group lost 7.4 ± 1.7 kg; 83% of this weight loss was fat mass, 17% was fat-free mass. Subjects in the control group lost some weight too (2.1 ± 1.5 kg). Resting metabolic rate (RMR) (MJ/day) decreased in the ER group (P < 0.001). In this group the thyroid hormone triiodothyronine (T3) decreased (P < 0.001), while reverse T3 (rT3) increased (P < 0.05). ADMR decreased significantly. It has been concluded that under conditions of a controlled moderately energy restricted diet in daily life a significant weight loss can be induced, similar to that observed after a balanced dietary deficit, providing 5 MJ/day. In addition, moderate energy restriction induces a decrease in fat-free mass and a fall in RMR.

INTRODUCTION

Many investigations have been done to document the adaptations of energy expenditure
response to very-low calorie diets (VLCD's), providing approximately 2.1 MJ/day, in obe
subjects.[1-3] There is general agreement that these diets can induce: a rapid weight lo:
suppression of the resting metabolic rate (RMR) and a reduction of the thyroid hormo
triiodothyronine (T3).[4] However, the adaptation to decreased energy intake might
different in subjects who are in a more normal weight range. Dieting has become a way
life for many people. Many slightly overweight people as well as people who percei
themselves as overweight are trying to lose some weight. Several studies have report
about the effects of low-fat diets on energy intake compensation.[5-7] Reports on the capac
of energy expenditure to adapt to a moderate decrease in energy intake in normal-weig
healthy individuals are scarce, especially those performed under controlled conditions. T
effects of a moderate energy deficit (3,350 kJ/day) for 3 weeks in normal weight studen
as well as the results of 12 weeks counseling[9] have been reported. Since these studies a
either short-term or not performed under dietary-controlled conditions we studied the eff
of a 10-week controlled moderately energy-restricted (aimed at 80% of habitual) diet
energy expenditure and body composition in healthy non-obese men.

MATERIALS AND METHODS

Subjects

Twenty-four apparently healthy men, aged 43 ± 5 yr (range 35-50 yr) with a mean BMI
24.6 ± 1.8 kg/m^2 (range 20.6-27.2 kg/m^2) participated in this study. All subjects had a stal
weight during the past year, normal routine clinical chemistry and were non-smoking. Th
had normal dietary habits (no vegetarian, macrobiotics etc.) and no extreme level
reported energy intake (9.3-13.2 MJ/day). Each subject was medically screened on the ba
of a health questionnaire and a medical examination. Informed consent was obtained fr
each subject and the research protocol was approved by the Institute's external Medi
Ethical Committee.

Experimental design

A detailed description of the study has been published elsewhere (Chapter 3).[10] Habit
energy intake was estimated by means of a 7-day dietary record before the study start
The total experiment lasted 12 weeks. Subjects were randomly assigned to two groups
control group (8 subjects) and an energy-restricted group (ER group; 16 subjects). Th
groups were matched on age and BMI. During the first two weeks of the study (run

period) all subjects received a weight-maintaining test diet based upon the outcome of the dietary record. Since energy intake differs among individuals, subjects were divided into 6 'energy groups' with a stepwise increase of approximately 770 kJ/day, ranging from 9,304 to 13,147 kJ/day. When subjects lost more than 1 kg/week during this run-in period they were reclassified into a higher energy group.

After these two weeks the 8 control subjects were kept on their weight-maintaining diet for the next ten weeks, while the other 16 subjects received a diet that contained 80% of the energy of their habitual (weight-maintaining) diet, and micronutrient levels of at least 100% their recommended dietary allowances (RDAs). Energy restriction was achieved by substituting low-fat and artificially sweetened products for ordinary products (i.e. substituting low-fat margarine for margarine, light soft drink for soft drink, artificial sweetener for sugar, low-fat coffee cream for coffee cream, salad dressing for mayonnaise, and skimmed yoghurt for whole yoghurt). The relative contribution of carbohydrates, fat and protein to total energy intake was 51%, 34%, 15% respectively for the control group and 47%, 36%, 17% respectively for the ER group. All foods and drinks to be consumed during these twelve weeks were supplied by the Institute. Subjects came to the Institute every evening to have dinner (cycle of 3 menus) and to receive the food for the next 24 hours. The subjects were not allowed to eat or drink anything else (except water) but the diet supplied by the Insitute. The subjects continued daily life habits during the study, and were asked to maintain physical activity at a constant level. In studies like this, compliance is difficult to measure. However, subjects in the ER group were expected to loose weight. Therefore, compliance was stimulated as much as possible by weighing all subjects regularly and by using a daily questionnaire, which included items like 'have you eaten all the food that you received?', 'have you eaten anything besides the food that you received?'.

The subjects were weighed every week. Body composition, urinary creatinine excretion and the thyroid hormones 3,5,3'-triiodothyronine (T3), reverse T3 (rT3), thyroxine (T4) and thyrotropin releasing hormone (TSH) were determined at the end of the run-period and at the end of the experiment. Resting metabolic rate (RMR) was measured twice before and twice at the end of the experimental period. The mean of the two measurements was used as a variable in the analysis. Average daily metabolic rate (ADMR) was measured in eight subjects, randomly chosen from the ER group, over two weeks, during the run-in period and during the last two weeks of the study.

Methods

Body composition. The subjects were weighed to the nearest 0.1 kg every week on a balance (ED-60-T; Berkel, Ridderkerk, The Netherlands) before dinner, while wearing underwear. Body composition was estimated from the three-compartment model of Siri[11] which combines body density with total body water. This technique has been shown to

improve the precision of body fat estimates over that obtained from either densitometry total body water alone.[11] Body density was measured using the hydrostatic weighi technique of Brozek et al.[12] Underwater weight was determined to the nearest 0.1 kg by balance (SK; Berkel, Ridderkerk, The Netherlands) while the residual lung volume w determined simultaneously by helium dilution and a spirometer (Volutest, Mijnhar Bunnik, The Netherlands). Total body water was determined by deuterium dilution. Subjec drank a weighed dose of labeled water (0.1 g ^2H_2O per kg estimated body water (from ag and sex-specific formula's[13]), resulting in an excess enrichment of 100 ppm) after emptyi the bladder at 22:00. This was the baseline urine sample. Another urine sample w collected the next morning from the second voiding. This 10 h sampling time is a preferab protocol for determining total body water as compared with 4 h and 6 h equilibrati times.[14] Total body water was calculated as the deuterium dilution space divided by 1.(correcting for exchange of the deuterium label with nonaqueous hydrogen of body solids The values of body density and body water (as a percentage of body mass) were used calculate body fat in the following equation:[11]

$$\%\text{body fat} = (2.118 / \text{density}) - (0.78 \times \%\text{body water}) - 1.354.$$

Creatinine. To measure creatinine excretion subjects collected urine over 24 h at t end of the run-in period and at the end of the experiment. Creatinine was analysed usi a commercially available kit (enzymatic PAP; Boehringer, Mannheim, Germany) anc Hitachi-911 autoanalyser.

Thyroid hormones. Serum T4 and T3 levels were analysed using a commerc radioimmunoassay (EURO/DPC, Llanberis, United Kingdom) according to the kit protoc Serum rT3 was analysed using a commercial radioimmunoassay (Techland, Lièg Belgium). TSH was analysed using an immunoradiometric assay (IRMA) (Behrin Marburg, Germany).

Resting metabolic rate. RMR was measured in the morning after the subjects h stayed overnight in the metabolic ward of the Institute. O_2 consumption (paramagne analyser, Beryl 102; Cosma, Igny, France) and CO_2 production (AR-400 infrared g analyser; Anarad, Santa Barbara, CA, USA) was measured under thermoneutral temperatu conditions in the fasting state on four occasions, twice during the run-in period and tw at the end of the experiment. O_2 and CO_2 analysers were calibrated against standardized g mixtures every morning. While lying for 30 minutes in supine position, the subjects w breathing through a low-resistance breathing valve (#2700; Hans Ruldolph, Kansas C MO, USA). Weir's[16] formula was used for calculating RMR.

Average daily metabolic rate (ADMR). ADMR was measured in eight subjects fr the ER group using doubly labeled water. These subjects were given a weighed dose c

mixture of ^2H_2O and $H_2^{18}O$ after collecting a background urine sample. The dose was calculated to create an excess of 150 ppm ^2H and 300 ppm ^{18}O. Further urine samples were collected on days 1, 8 and 15 after dosing from the second voiding in the morning. Isotope abundances in the urine samples were measured with an isotope-ratio mass spectrometer (Aqua Sira; VG Isogas Ltd, Middlewich, Cheshire, United Kingdom) and CO_2 production was calculated as previously described.[17] The analytical precision was 0.2 ppm for ^2H and 0.4 ppm for ^{18}O.

The *Physical activity level (PAL)* was calculated as the ratio ADMR/RMR.

Statistics

BMDP statistical software, version: 1990 vax/vms (Los Angeles, CA, USA) was used to detect changes within as well as between the groups, and to calculate correlations between parameters. Changes within the groups were tested for significance with the paired Student's t-test. Differences in changes between the two groups were tested using the unpaired Student's t-test. Relationships between two variables were calculated by Pearson's linear correlation. Analysis of covariance using FFM as the covariate was used to adjust for differences in body composition when comparing RMR values.

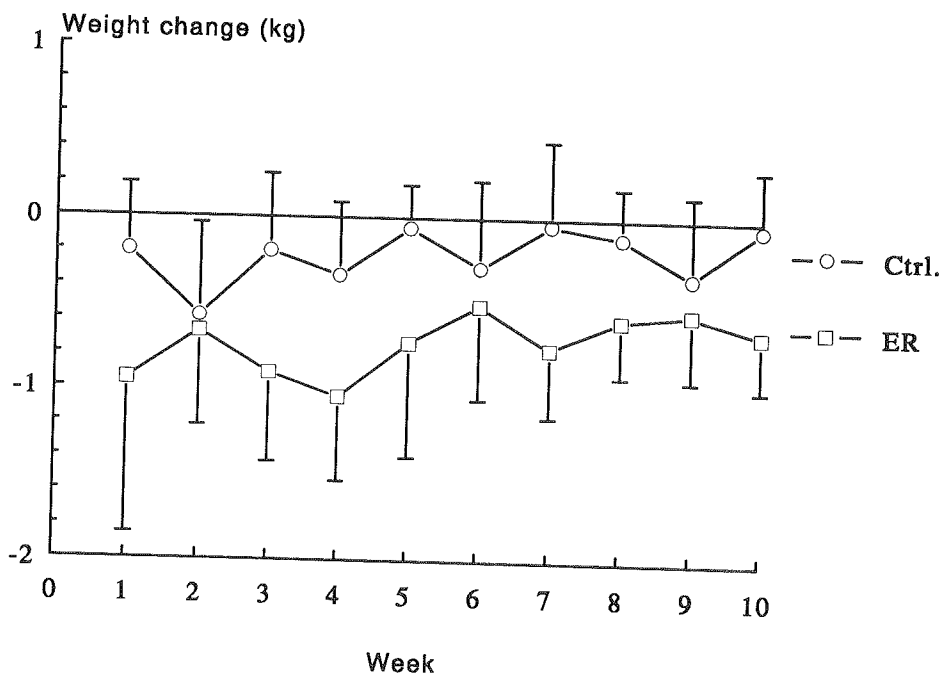

Figure 5.1. Rate of weight loss during the study. Data are presented as x̄ ± SD.

RESULTS

Table 5.1 presents the results on body composition and energy metabolism. Since total bod
water measurements were not completed in two subjects, the results of body fat (FM) an
fat-free mass (FFM) in the ER group represent 14 subjects. As expected, weight loss in th
ER group was substantial (7.4 ± 1.7 kg). Subjects in the control group lost some weight to
(2.1 ± 1.5 kg) (Figure 5.1). About 83% of the weight loss in the ER group appeared to b
loss of fat mass, and the remaining 17% of the weight loss was attributed to loss of FFN
The ER group lost significantly more fat and FFM than the control group. Urinar
creatinine excretion had not changed after the experimental period.

Table 5.1. Summary of the results of energy intake, energy expenditure and body composition. Mea
values and standard deviations of the control group and the energy restricted group before (aft
a two-week run-in period) and of the change after the experimental period are presented.

*** P < 0.001, ** P < 0.01, * P < 0.05 within group.

Energy restriction led to significantly decreased RMR (MJ/day) values in both groups. This decrease in RMR tended to be stronger in the ER group. RMR correlated to kg FFM both before (r = 0.613; P = 0.001) and after the study (r = 0.657; P < 0.001). However, as tested with analysis of covariance, after the period of energy restriction the intercept of the regression line had decreased (P < 0.001) (Figure 5.2). No effects of energy restriction on T4 and TSH were observed. T3 concentration decreased significantly in both groups. The differences in changes between the two groups were not significant. rT3 levels increased in the ER group. The increase in rT3 levels correlated with the decrease in RMR (r = −0.431, P = 0.036).

As shown in Table 5.2, ADMR, as measured in 8 subjects, was higher than energy intake during the run-in period which was based on the 7-day dietary record, indicating some degree of underreporting. During the experimental period ADMR decreased significantly. PAL tended to decrease. Table 5.3 presents the rate constants and dilution spaces for ^{18}O and ^{2}H.

DISCUSSION

The basis for restricting one's energy intake is knowledge of his/her habitual intake. Th
availability of the doubly labeled water technique permits the measurement of ADMR ov
one to two weeks. Since estimation of ADMR by the doubly labeled water method
expensive, it was performed in eight subjects from the ER group only. Habitual energ
intake was estimated by means of a 7-day dietary record by all subjects. To gain som
insight into the difference between reported intake and energy expenditure, these tw
methods were compared. Reported energy intake appeared to be 82.5% of the ADMF
Underreporting is a common phenomenon in recording dietary intake,[18] and seemed to hav
occurred also in our study, despite the fact that the subjects were aware of the importanc
of the dietary record. Therefore some subjects might be restricted in their energy intake b
more than 20%. In these eight subjects the average level of energy restriction was 33⁹
(range 18-42%). This result might be a reflection of the whole ER group. Since the contr
group lost some weight as well, underreporting might also have played a role in this grou

The main goal of this study was to evaluate the adaptation to a moderate restrictic
in energy intake in non-obese subjects. Many studies on the effects of an energy-restricte
diet are performed in obese subjects receiving very low caloric diets, or in anorexia nervo
patients.

kO = rate constant for ^{18}O; kH = rate constant for ^{2}H; nO = dilution space for ^{18}O; nH = dilution space for ^{2}H.

However, data on the effects of moderate ER in non-obese man have, to our knowledge, only been reported by two groups: Heyman et al.[8] provided normal-weight subjects with a diet with a gross energy deficit of 3.37 MJ/day for 21 days, i.e. approximately 20% ER. Subjects lost about 2.0 kg body weight. The authors noted that energy balance is regulated by changes in body energy stores (63%) and energy expenditure (37%). However, these data reflect the results of only the short-term effects of moderate ER. Garby et al.[9] asked normal-weight subjects to reduce their energy intake by 25% over a period of 12 weeks. No changes were observed in 24 h energy expenditure and pattern of physical activity. Mean change in body weight was –2.9 ± 3.0 kg. When the recorded food intake was assumed to be correct, this weight loss was far below that calculated and indicates non-compliance with the diet. Since little information is available about the effects of longer-term moderate energy restriction under controlled dietary conditions our study was performed, especially to investigate the adaptation of energy metabolism to a reduced energy intake.

One of the questions was whether the subjects would regain a new stable weight after a period of moderate energy restriction. In the classical semi-starvation study by Keys et al.,[19] in which the subjects received a 50% energy-restricted diet for 24 weeks, the rate of weight loss did not decrease during the first 16 weeks but was close to zero at the end of the study. Since this 50% reduction in energy intake appeared to introduce several negative health effects (symptoms of lethargy, apathy and listlessness), a level of 20% energy restriction for 10 weeks was chosen. However, since underreporting of food intake has taken place the actual level of energy restriction was about 33%. As shown in Figure 5.1, subjects were still losing weight at the end of the experimental period and there was no tendency to stabilization. Whether or when these subjects would reach a new stable

weight (steady state), and what this new weight would be, is uncertain. The control group, submitted to a mild level of energy restriction due to underreporting, did show weight stabilization as rate of weight loss was close to zero at the end of the study (Figure 5.1). Linear regression revealed a significant relationship between week and weight change ($r = 0.602$, $P = 0.032$) in the control group.

To assess when the ER group would reach a steady state a computer simulation model can be used.[20] This model simulates changes in FM and FFM using energy intake (EI) and physical activity as input variables. EI can be set at a chosen value or calculated from dietary intake with a data base on the net energy of foods. Physical activity can be set at a chosen multiple of basal metabolic rate (BMR) or calculated from the activity budget with a data base on the energy cost of activities in multiples of BMR. BMR is calculated from FFM and FM and, if necessary, FFM is calculated from body weight, height, sex and age, using emperical equations. The model uses existing knowledge on the adaptation of energy expenditure (EE) to a disbalance between EI and EE, and to resulting changes in FM and FFM. Mobilisation and storage of energy as FM and FFM is a function of the relative size of the deficit (EI/EE) and of the body composition. The model was validated with three recent studies measuring EE at a fixed EI during an interval with energy restriction, overfeeding and exercise training, respectively. Discrepancies between observed and simulated changes in energy stores were within the measurement precision of EI, EE, and body composition. Introduction of our data in this computer simulation model revealed that, on the long term, this 33% level is too high to adapt to. Even when a level of 20% energy restriction was induced, then, according to this simulation model, the subjects would still be in negative energy balance (–940 kJ/day) after a period of one year. Body weight would be approximately 59 kg, and subjects would have about 5.6% body fat.

25% FFM/75% FM-loss is considered as a 'rule of thumb' in weight-loss studies.[4] In the study presented 17% of weight loss was attributed to loss of FFM which might be a favourable effect of moderate ER. FFM has also been calculated from urinary creatinine excretion.[21] Urinary creatinine excretion before the experimental period correlated moderately with FFM ($r = 0.445$; $P = 0.029$). Despite some loss of FFM in the ER group no significant change in creatinine excretion could be detected. This may be due to the small size of the group, and to the fact that only one 24-hour urine was collected. Creatinine excretion is affected by the amount of meat in the diet. In this study food intake was completely controlled since all food, including meat, was supplied by the Institute, and was kept constant during the entire study.

From the measurements performed in all subjects it is clear that the subjects reacted to the moderate energy deficit by lowering resting energy metabolism (–13%) and by losing 7.4 ± 1.7 kg body weight in ten weeks, which means that mean rate of weight loss was approximately 0.74 kg/week. Weight losses, induced by balanced deficit diets (BDD

providing 5 MJ/day, of 0.72 kg/week and 0.70 kg/week after a period of 10 weeks have been observed[22,23] which is not lower than that observed in our study. Since energy expenditure in obese women has been reported to be about 11 MJ/day,[24,25] these BDD's induce approximately 50% ER. It is not very likely that the 33% ER (providing ca. 9.2 MJ/day), is as effective in loosing weight as 50% ER induced by BDD's (providing ca. 5 MJ/day). This can only be explained by supposing that the participants in these BDD-studies did not adhere completely to their prescribed diets, and most probably decreased their level of ER to approximately 30%.

FFM correlated significantly with RMR (MJ/day) both before (P = 0.01) and after (P < 0.001) the experimental period. However, after the experimental period the intercept of the regression line had decreased significantly (Figure 5.2). This might indicate an enhanced metabolic efficiency after a period of energy restriction, related to the changes in thyroid function (i.e. decreased T3 and increased rT3 levels), a phenomenon also seen after VLCD.[26] However, the fall in RMR (MJ/day) of 13.3% was less than that reported after VLCD,[4] but is comparable to that observed after BDD.[27]

From the difference between ADMR measured before and energy intake during the intervention period in those 8 subjects who consumed the doubly labeled water, the total energy deficit in the energy-restricted period was calculated to be 333.7 MJ. As shown in Table 5.2, these 8 subjects lost 6.8 kg body weight (5.8 kg fat mass; 1.0 kg FFM) on average. The energy values for the two body constituents, fat mass and FFM, are 37.7 and 3.68 MJ/kg respectively.[28] Thus, the energy content of the body decreased by $5.8*37.7 + 1.0*3.68 = 222.4$ MJ in 10 weeks of energy restriction. This indicates that approximately 111.3 MJ (333.7 − 222.4) was saved by decreasing energy expenditure (ADMR). We may therefore conclude that the decrease in body energy stores compensated for 67% and the decrease in ADMR for 33% of the energy deficit on average. The decrease in ADMR was partly due to decreased activity, partly to a decreased RMR, and partly to a decreased diet-induced thermogenesis (DIT) assumed to be 10% of energy intake. These findings are consistent with those observed by Heyman et al.[8] The decrease in energy expended on physical activity might be the consequence of either reduced physical activity, or decreased expenditure on work due to reduced body weight, or both. The reduction in RMR may be due to a loss of metabolizing tissue, or to a change in the rate of metabolism of the remaining tissue, or to a combination of both factors.

To summarize, this study shows that, under controlled dietary conditions, a moderately energy restricted diet (33%), can lead to an average rate of weight loss of 0.74 kg/week in non-obese men. In addition, moderate energy restriction induces a loss of FFM, as well as a decreased RMR which is associated with decreased T3 concentrations. These results are comparable to those of studies providing a balanced dietary deficit (5 MJ/day) in obese.

ABSTRACT

Impaired fibrinolytic activity has been reported in the elderly and is thought to play a role in the aetiology of cardiovascular disease, one of the leading causes of death in most western countries. Since restriction of energy intake has been demonstrated to act beneficially on the ageing process in a variety of species, we studied the effect of a 10-week moderately energy-restricted regimen (80% of habitual) on PAI activity, PAI-1 antigen, tPA activity and tPA antigen in non-obese middle-aged men. Moreover, the relationship between these fibrinolytic markers and glucose tolerance was investigated. Weight loss in the energy restricted group (ER group; n = 16) was considerable (−7.4 ± 1.7 kg; P < 0.001). Subjects in the control group (n = 8) lost some weight too (−2.1 ± 1.5 kg; P < 0.01). Fasting glucose levels decreased in the ER group (−0.31 ± 0.48 mM; P < 0.05) which was correlated with the extent of weight loss (P < 0.01). Baseline insulin levels at 2 hours after an oral glucose load correlated with baseline PAI activity (P < 0.001) and PAI-1 antigen levels (P < 0.001). PAI activity decreased in the ER group (−2.94 ± 2.90 IU/ml; P < 0.001) in particular in subjects with a high baseline PAI activity (> 9 IU/ml). Furthermore, ER lead to decreased PAI-1 antigen concentration (P < 0.05), a nonsignificant increase in tPA activity as well as a decrease in tPA antigen concentration (P < 0.001). All these changes were more clear in those subjects with a high baseline PAI activity. These results suggest that 10 weeks of moderate energy restriction has a profibrinolytic effect in non-obese middle-aged men, at least in subjects with higher baseline PAI activity (> 9 IU/ml). Moreover, in line with the suggestion that a high PAI activity goes together with insulin resistance, a relationship between the insulin concentration after a glucose load and PAI activity was found.

INTRODUCTION

Restriction of the energy intake (ER), with adequate intake of essential nutrients, is up
now the only dietary regimen known to have a beneficial effect on the ageing process
rodents, ER prolongs life span and delays or prevents the onset of several age-relat
diseases.[1] The mechanism behind this process is still largely unknown and many effo
are now being directed at unravelling the causal relationship between energy metabolis
and the ageing process. Since ER has been demonstrated to be effective in a variety
species these beneficial effects might also hold for human beings on an appropria
energy-restricted regimen. Obviously, it is difficult to assess the potential effect of ER
human beings in an experimental design. However, as a first approach, the feasibili
and potential health risks/benefits of a moderately energy-restricted diet can be assesse
Another approach could be to study the effects of ER on physiological syster
associated with the ageing process.

   Cardiovascular disease is one of the leading causes of death in most weste
countries and has been related to the ageing process. Impaired fibrinolytic activity h
been reported in the elderly[2] and is thought to play a role in the pathogenesis/aetiolo;
of cardiovascular disease. The activity of the fibrinolytic system depends on competi
processes in a dynamic equilibrium involving circulating activators of plasminoge
primarily tissue-type plasminogen activator (tPA), and circulating inhibitors of the
activators, primarily plasminogen activator inhibitor type 1 (PAI-1). Since ener;
restriction has a beneficial effect on the ageing process it may also have an effect
haemostatic function. Therefore, as part of a study into potential benefits and/or risks
a 10-week moderately energy-restricted regimen in non-obese middle-aged ma
activities and concentrations of indicators of the fibrinolytic system (PAI activity, PAI
antigen, tPA activity, and tPA antigen) were analysed. In addition, since it has be
suggested that PAI-1 contributes to the increased cardiovascular risk together wi
insulin resistance,[3] the relationship between fibrinolytic markers and glucose toleran
was investigated.

SUBJECTS AND METHODS

Subjects
Twenty-four apparently healthy men aged 43 ± 5 yr (range 35-50 yr) with a mean boo
mass index (BMI) of 24.6 ± 1.8 kg/m^2 (range 20.6-27.2 kg/m^2), participated in th
study. All subjects had a stable weight during the past year, normal routine clinic
chemistry and were non-smoking. They had normal dietary habits and no extreme lev

of energy intake (9.3-13.2 MJ/day; i.e. 97-214 kJ/kg/day). Each subject was medically screened on the basis of a health questionnaire and a medical examination. Informed consent was obtained from each subject and the research protocol was approved by the Institute's external Medical Ethical Committee.

Experimental design

A detailed description of the study has been published elsewhere (Chapter 3).[4] In short, the habitual energy intake was estimated by means of a 7-day dietary record before the study started. The total experiment lasted 12 weeks. Subjects were randomly assigned to one of two groups: a control group (8 subjects) and an energy-restricted group (ER group; 16 subjects). These groups were matched on age and BMI. During the first two weeks of the study (run-in period) all subjects received a weight-maintaining test diet based upon the outcome of the dietary record. Since energy intake differs among individuals, subjects were divided into 6 'energy groups' with a stepwise increase of ca. 770 kJ/day, ranging from 9,304 to 13,147 kJ/day. When subjects lost more than 1 kg/week during this run-in period they were reclassified into a higher energy group.

After these two weeks the 8 control subjects were kept on their weight-maintaining diet for the next 10 weeks, while the other 16 subjects received a diet that contained 80% of the energy of their habitual (weight-maintaining) diet, and micronutrient levels of at least their recommended dietary allowances (RDAs). Energy restriction was achieved by substituting low-fat and artificially sweetened products for ordinary products. This implied that the relative contribution of carbohydrates, fat and protein to total energy intake was 51%, 34% and 15% respectively for the control group and 47%, 36% and 17% respectively for the ER group. All foods and drinks to be consumed during these 12 weeks were supplied by the Institute. The subjects were not allowed to eat or drink (except water) anything but the diet supplied.

At the end of the run-in period and at the end of the experiment blood samples were drawn after an overnight fast for the analysis of indicators of the fibrinolytic system, as well as for fasting (t = 0) glucose and insulin concentrations. Thereafter, an oral glucose tolerance test (OGTT) was performed according to the WHO protocol:[5] 2 hours after an oral glucose load (75 g in 250 ml water, which had to be drunk within 15 minutes) another blood sample (t = 120) was drawn for the analysis of glucose and insulin concentrations.

Methods

Plasma glucose concentrations were analysed with a commercially available kit (Boehringer Mannheim Diagnostica; Hitachi 911, Japan). Plasma insulin concentrations were analysed with a commercial radioassay (Pharmacia, Roosendaal, The Netherlands)

according to the kit protocol.

For the analysis of fibrinolytic factors blood was taken into ice-chilled tubes from the intermedian cubital vein by a venoject system. After centrifugation for 10 min at 1700xg and 4°C the plasma was collected, snap frozen and stored at −80°C until analysis.

To measure PAI activity, PAI-1 antigen and tPA antigen blood was collected in CTAD buffer (0.11 M citrate, 15 nM theophylline, 3.7 mM adenosine and 0.198 mM dipyridamole; Becton Dickinson, Meylon, France). For measuring tPA activity blood was collected in Stabilyte tubes (Biopool, Umeå, Sweden). PAI activity was measured by a titration method with two-chain tPA according to the method of Verheijen et al.[6] Results are expressed relative to pooled plasma: 100% activity corresponds to neutralization of 7.6 IU/ml of tPA. PAI-1 antigen was measured by means of an enzyme linked immunosorbent assay (ELISA) (Coalize® PAI-1/Innotest PAI-1, Chromogenix AB, Möndal, Sweden[7]). tPA activity was measured with a bioimmunoassay for t-PA (Coatest® BIA t-PA, Chromogenix[8]). tPA antigen was measured with the Imulyse t-PA™ method (Biopool).

Statistics

BMDP statistical software was used to detect changes within and between the groups and to calculate correlations between parameters. Changes within the groups were tested for significance with the paired Student's t-test. Differences in changes between the two groups were tested with the unpaired Student's t-test. Relationships between two variables were calculated with Pearson's linear correlation coefficient. Since the control group lost some weight too, correlations were calculated for the entire subject population (n = 24).

RESULTS

Baseline subject characteristics (age, body weight, BMI and OGTT) as well as the change (Δ) after the experimental period are presented in Table 6.1. Both groups lost weight. However, as could be expected, subjects in the ER group lost significantly more weight, resulting in a drop in BMI. Fasting glucose levels (t = 0) significantly decreased in the ER group, with no significant difference between the ER group and the control group. This decrease in the fasting glucose level correlated with the extent of weight loss (r = 0.531, P = 0.008), and with the change in BMI (r = 0.576, P = 0.003). With regard to the parameters of the OGTT, no other significant changes were observed.

[a] subgroup 1: baseline PAI activity ≤ 9 IU/ml, control group n = 5, ER group n = 9;
subgroup 2: baseline PAI activity > 9 IU/ml, control group n = 3, ER group n = 7.
* = P < 0.05; ** = P < 0.01; *** = P < 0.001.

The results on fibrinolytic parameters are presented in Table 6.2. At baseline, these parameters did not differ significantly between groups. Energy restriction resulted in significantly lower PAI activity. Further inspection of the data (Figure 6.1) showed that the decrease of PAI activity in the ER group was modest in subjects (n = 9) with baseline PAI activity levels ≤ 9 IU/ml (subgroup 1), but was most marked in subjects (n = 7) with a baseline PAI activity higher than 9 IU/ml (subgroup 2). PAI-1 antigen level decreased significantly in the ER group. In this group, the high-PAI subgroup (subgroup 2) showed the strongest decrease in PAI-1 antigen level but this decrease was not significant (P = 0.08). tPA activity decreased significantly in the control group but not in the ER group. However, when baseline PAI activity level was taken into account, tPA activity increased significantly in subgroup 2. tPA antigen decreased significantly in both the control and the ER group, although the effect was more outspoken in the ER group, especially in subgroup 2.

A similar subgroup analysis was also performed for the control group although the subgroups are relatively small (n = 3; n = 5) for statistical analysis.

Figure 6.1. Relationship between PAI activity at baseline and at the end of the intervention period.
— y=x; -----PAI = 9 IU/ml.

Correlation coefficients were calculated between baseline values as well as between changes in the parameters analysed. Baseline PAI activity was found to be inversely correlated to tPA activity (r = –0.683, P < 0.001), and significantly related to PAI-1 antigen concentration (r = 0.675, P < 0.001) as well as to tPA antigen concentration (r = 0.640, P < 0.001). Baseline insulin level at t = 120 was significantly related to baseline PAI activity and antigen levels. Baseline BMI was not correlated with baseline PAI activity, but the decrease in BMI correlated slightly but significantly with the decrease in PAI activity (Table 6.3).

Table 6.3. Correlations (r) between baseline fibrinolytic factors and some physiolocal parameters (BMI and OGTT), as well as between changes in these parameters (n = 24).

	PAI activity	PAI-1 antigen	t-PA activity	t-PA antigen

DISCUSSION

The aim of this study was to look after potential health risks or benefits of the application of a moderately energy-restricted diet with special regard to fibrinolytic factors. High PAI activity, leading to decreased fibrinolytic activity, can predict coronary thrombosis.[9] There is general agreement on lower fibrinolytic activity in obesity: in observational studies an inverse relationship between obesity and fibrinolytic activity,[10,11] as well as a positive correlation between BMI and PAI activity[12,13] has been found. From a case-control study it appeared that obese subjects had lower fibrinolytic activity associated with elevated PAI-1 concentrations which, in turn, correlated with increased concentrations of insulin.[14] The small range in BMI in our study probably explains why

we did not find an association between BMI and fibrinolytic factors, as compared to tⁱ
large range (16-39 kg/m²) in the studies mentioned.

Intervention studies into the effects of ER and/or weight loss on the fibrinolyt
system have especially been reported for obese but hardly for lean subjects, and we
focused either on very-low-caloric-diets (VLCD) or on surgical treatment. In obe:
subjects (BMI > 30 kg/m²), VLCD for 3 months[15] or 6 months[16] has been reported
lower factor VII,[15,16] PAI activity,[15] PAI-1 antigen[16] as well as tPA antigen[16] which
associated with marked weight loss. Surgical treatment resulted in a mean decrease
body weight of 64 kg at 12 months and was accompanied by significant reductions
factor VII, fibrinogen concentration and PAI activity.[17] From these intervention studies
can be concluded that fibrinolytic activity increases after severe weight loss in the obes
However, dieting also occurs among lean subjects. Ogston[10] noted that a diet (
590 kJ/day for 3 days increased fibrinolytic activity in non-obese subjects. To oⁱ
knowledge, no studies have reported on the effects of moderate energy restriction
non-obese subjects. Therefore, this is the first longer-term study into the effects (
moderate energy restriction on fibrinolytic factors showing that even moderate energ
restriction has beneficial effects on fibrinolytic factors, at least in subjects with highⁱ
PAI activity (> 9 IU/ml). Although this decrease could be ascribed to a 'regression
the mean', it is noteworthy that PAI activity did not decrease in the control grou
(Figure 6.1).

In the present study the effect of ER on lipid profile was also measured, the resuⁱ
of which are presented elsewhere[4]. Briefly, no significant of ER on fasting triglycerid
total cholesterol, LDL-cholesterol and HDL-cholesterol concentrations were observe
using students t-test. However, the decrease in body weight was significantly relatє
with an increase in HDL-cholesterol. PAI-1 antigen has been associated with sever
cardiovascular risk factors including hypertension, hypertriglyceridemia, gluco:
intolerance and type II diabetes mellitus.[18] In this study PAI-activity correlatє
significantly with fasting triglyceride, total cholesterol and LDL-cholesterⁱ
concentrations (r = 0.743, P < 0.001; r = 0.506, P = 0.012 and r = 0.514, P = 0.01
respectively in 24 subjects). In addition, in our study subjects with a PAI activiⁱ
> 9 IU/ml (n = 10) did not differ in BMI or in systolic or diastolic blood pressure bⁱ
had significantly higher baseline glucose levels at t = 0 (P = 0.015) and triglyceridє
concentration (P = 0.038) and tended to have higher insulin levels at t = 12
(P = 0.059). This association suggests a link between PAI-1 antigen and insulⁱ
resistance (i.e. 'resistance to the glucose-stimulating effects of insulin in key organs suⁱ
as muscle tissue, liver and fat, leading to higher glucose concentrations, albeit within tⁱ
normal ranges'[19]). This link has been studied by Potter van Loon et al.[3] by means of
sequential hyperinsulinemic euglycemic clamp study in obese subjects. They found th

PAI-1 antigen correlated significantly with peripheral insulin resistance. In our study significant correlations between baseline fasting PAI activity/antigen and glucose as well as insulin levels at two hours after a glucose load were observed. This finding suggest a similar relationship between insulin sensitivity and PAI activity, even in lean subjects. After 10 weeks of moderate energy restriction the correlation between PAI activity and insulin at t = 120 was less obvious but still significant (r = 0.565, P = 0.006), probably due to smaller ranges.

The mediator between insulin and PAI is not clear yet.[20,21] In vitro, the secretion of PAI-1 by cultured hepatocytes in promoted by insulin.[9]

In conclusion, this study shows that moderate energy restriction in non-obese men with PAI activity levels higher than 9 IU/ml has beneficial effects on fibrinolytic factors. In addition, before the intervention period, PAI activity was significantly correlated with insulin and glucose levels at two hours after a glucose load, in agreement with the suggestion that higher PAI activity encounters insulin resistance. Since moderate energy restriction has a beneficial effect on the ageing process, and impaired fibrinolytic activity is associated with ageing, energy restriction might at least in part delay the ageing process by increasing fibrinolytic activity.

Since this study presents the results of a 10-week energy-restricted diet we can only speculate on the longer-term effects. However, it is very difficult to conduct controlled feeding studies for periods longer than 12 weeks. In this study we aimed at 20% ER, but due to underreporting of habitual energy intake, as indicated by weight loss in the control group, the imposed energy restriction was probably higher than 20%. Since subjects were still losing weight at the end of the intervention period with no sign of a tendency to stabilize, we feel that the imposed level of energy restriction might be too high and not feasible as a long-term intervention. Therefore, in future studies, we will focus on longer- term feasibility of a more moderate ER regimen and under free-living conditions. However, the results of this study clearly show that moderate ER is also relevant in lean subjects and has a health-potentiating effect.

Since this study presents only fibrinolytic factors, and not true fibrinolytic activity, it would also be worthwhile to study the effect of a period of moderate energy restriction on true fibrinolytic activity. However, from the results of this study, i.e. a decreased PAI activity and in increased tPA activity in the high-PAI subgroup, an increased true fibrinolytic activity might be expected. Since this study shows that moderate energy restriction acts profibrinolytically in healthy non-obese men, it would also be valuable to study whether these results are representative for other populations, including those with higher risks for cardiovascular disease.

Short-term moderate energy restriction does not affect indicators of oxidative stress and genotoxicity in humans

ABSTRACT

Restriction of energy intake (ER), without malnutrition of essential nutrients, has repeatedly been demonstrated to increase longevity in rodents. Several hypotheses have been put forward to explain this phenomenon. In the 'antioxidant theory of ageing' the unbalance between the generation of free radicals and free radical scavenging has been suggested to be a main causal agent in the ageing process. From this point of view the anti-ageing effect induced by ER in animals might be due to the lower rate of free-radical production and related damage induced by a lower metabolic rate. The anti-ageing effects of ER might also occur in humans. This study explored the short-term effects (10 weeks) of a moderately energy-restricted diet (80% of habitual) in 24 non-obese middle-aged men (16 ER subjects, 8 controls) on resting metabolic rate (RMR) and indicators of the primary antioxidant defence system, oxidative stress and genotoxicity. RMR decreased significantly in both groups, even when adjustments were made for the change in body composition. No significant effects were observed for the indicators of oxidative stress or for indicators of genotoxicity. Erythrocyte catalase activity decreased significantly and similarly in both groups. The activities of glutathione peroxidase and superoxide dismutase did not change. Blood vitamin C concentrations increased (+13.4±14.0 μmol/L; P < 0.01) in the ER group. Changes in blood vitamin C correlated with the increases in urinary 8-hydroxy-deoxyguanosine (8OHdG) excretion in all subjects (n = 21; r = 0.478; P = 0.021). The change in urinary 8OHdG excretion also

correlated with the change in RMR (n = 21; r = 0.516; P = 0.017) when values we
expressed per kg fat-free mass. No differences between groups were found for chang
in plasma vitamin E, vitamin A or β-carotene concentrations. We conclude that 1
weeks of moderate ER did not affect indicators of antioxidative capacity, oxidative stre
and genotoxicity of humans. Since subjects were not in energy balance at the end of tl
study, no conclusions can be made with respect to long-term effects.

INTRODUCTION

Energy restriction (ER), without malnutrition of essential nutrients, has repeatedly bee
demonstrated to effectively and reproducibly increase longevity in rodents. Although E
retards many of the physiological changes associated with ageing, the mechanism(
responsible for the anti-ageing effects of ER are not well understood, which is also tru
for the basic causes of the ageing process itself. Among the many theories of ageing, tl
possibility that free radicals, generated by oxygen metabolism, are involved as ma
causal agents is receiving particular attention. Harman[1] formulated his 'free radic
theory of living' as early as 1954, when he postulated that ageing might be attributed
least in part to accumulative damage caused by radical generation associated wi
cellular metabolic activity. According to this theory, free-radical damage can by reduce
by lowering metabolic rate. This theory has been supported by studies from Cutler[2] wh
showed an inverse relationship between species-specific life span and metabolic rate.

Therefore, one of the causes underlying the anti-ageing effect induced by ER mig|
be a lower rate of free-radical production and related damage, induced by a low¢
metabolic rate.

In addition to the effect on metabolic rate, the beneficial effects of ER on tl
ageing process have been explained by a positive effect of ER on maintaining, or eve
increasing, the anti-oxidative defence system with age.[3] Free radicals are effectivel
scavenged by both radical-scavenging enzymes such as superoxide dismutase (SOD
catalase and glutathione peroxidase (GSH-Px), as well as by antioxidants such ¿
vitamins E and C and β-carotene.

Thus, the beneficial effects of ER on the ageing process may proceed through bo|
effects, i.e. by lowering the production rate and by effective scavenging of free radical
both resulting in lowering of oxidative stress. An intriguing question remains wheth¢
ER might also be beneficial in humans. Since ageing is a pleiotropic process, tl
anti-ageing effects of ER might also occur in human beings. However, it is ve|
difficult, if not impossible, to test this hypothesis in life-long controlled huma
experiments. The aim of this study was to investigate the effects of a 10-wee

moderately energy-restricted diet in non-obese middle-aged men on indicators of the primary antioxidant defence system (antioxidant enzymes as well as antioxidant vitamins), oxidative stress and of genotoxicity. The duration of the study was 12 weeks because, in our opinion, volunteers would not be willing to participate for a longer period of time under these controlled conditions. It was hypothesized that ER might increase anti-oxidative capacity or reduce oxidative damage, in parallel with a decrease in resting metabolic rate.

MATERIALS AND METHODS

Subjects:

Twenty-four apparently healthy men, aged 43 ± 5 (range 35-50 years) with a mean body mass index (BMI) of 24.6 ± 1.8 kg/m^2 (range 20.6-27.2 kg/m^2) participated in this study. All subjects had a stable weight during the past year, had a normal routine clinical chemistry profile and were non-smokers. They had normal dietary patterns and no extreme level of energy intake (9,300-13,200 kJ/day). Some physiological characteristics (body weight, BMI, resting metabolic rate) of the subjects are presented in Table 7.1. Each subject was medically screened through a health questionnaire and a medical examination. Informed consent was obtained from each subject and the research protocol was approved by the Institute's external Medical Ethical Committee.

Experimental design:

A detailed description of the experimental design has been published elsewhere (Chapter 3).[4] Briefly, the total experiment lasted 12 weeks. Subjects were assigned to two groups: a control group (n = 8) and an energy-restricted group (ER group; n = 16). Groups were matched on the basis of age and BMI. Habitual food intake was assessed by means of a 7-day dietary record. As calculated with the computerized Netherlands Food Composition Table (UCV/NEVO), habitual intake of saturated fatty acids (SFA), monounsaturated fatty acids (MUFA) and polyunsaturated fatty acids (PUFA), respectively was 17.3 ± 2.9%, 16.0 ± 2.0% and 6.6 ± 1.1% of total energy intake in the control group and 15.8 ± 2.2%, 15.4 ± 2.9% and 6.4 ± 1.3% of total energy intake in the ER group. The groups did not differ significantly for any of these fatty acid intakes.

During the first two weeks of the study (run-in period) all subjects received a weight-maintaining test diet based upon the outcome of their dietary record. Since energy intake differs among individuals, subjects were divided into 6 'energy groups' with a stepwise increase of ca. 770 kJ (i.e. 9,304; 10,073; 10,841; 11,610; 12,378 and 13,147 kJ/day respectively). When subjects lost more than 1 kg/week during this run-in

period they were reclassified into a higher energy group.

After these two weeks the 8 control subjects were kept on their weight-maintaining diet for the next ten weeks, while the other 16 subjects received a test diet that contained 80% of the energy of their habitual (weight-maintaining) diet, with micronutrient level of at least their Recommended Dietary Allowance (RDA). The 20% energy restriction was achieved by substituting low-fat and artificially sweetened products for ordinary products, such that the relative contribution of carbohydrates, fat and protein to total energy intake remained approximately the same. During the experimental period intake of SFA, MUFA and PUFA was calculated to be $13.6 \pm 0.3\%$, $13.2 \pm 0.5\%$ and $11.1 \pm 0.4\%$ of total energy intake in the control group and $14.2 \pm 0.1\%$, $13.8 \pm 0.2\%$ and $8.1 \pm 0.1\%$ respectively in the ER group, indicating that PUFA intake was lower in the ER group. Diets with the highest and lowest energy content were analysed for antioxidant micronutrients. Analyses of these extremes revealed that vitamin E intake was between 7.8 and 18.6 mg per day for the control group and between 9.3 and 10.7 mg per day for the ER group; vitamin C intake was between 97.4 and 136.1 mg per day for the control group and between 117.4 and 135.2 mg per day for the ER group; β-carotene intake was between 1.9 and 2.1 mg per day for the control group and between 1.9 and 2.0 mg per day for the ER group; selenium intake was between 39 and 52 μg per day for the control group and between 28 and 51 μg per day for the ER group.

All foods and drinks to be consumed during the 12-week study were supplied by the Institute. The subjects were not allowed to eat or drink (except water) anything but the food supplied.

Resting metabolic rate (RMR) was measured twice before and twice at the end of the experimental period. The mean of the duplicate measurements was used as a variable in the analysis. At the end of the run-in period and at the end of the experimental period body composition was measured and blood was drawn from fasting subjects for the analysis of variables related to oxidative stress (plasma malondialdehyde (MDA) oxidazibility of LDL (LDL-ox), and 8-hydroxydeoxyguanosine (8-OHdG) in both lymphocytes and urine), as well as for the indicators of anti-oxidative capacity (erythrocyte catalase, glutathione peroxidase (GSH-Px) and superoxide dismutase (SOD) activities as well as plasma vitamins C, E and A, and β-carotene concentrations).

Methods:
Resting metabolic rate. RMR was measured in the morning after the subjects had stayed overnight in the metabolic ward of the Institute. O_2 consumption (paramagnetic analyser Beryl 102; Cosma, Igny, France) and CO_2 production (AR-400 infrared gas analyser Anarad, Santa Barbara, CA, USA) were measured under thermoneutral temperature

conditions in fasting subjects on four occasions, twice during the run-in period and twice near the end of the experiment. O_2 and CO_2 analysers were calibrated against standardized gas mixtures every morning. While lying for 30 min in supine position, the subjects were breathing through a low-resistance breathing valve (#2700; Hans Ruldolph, Kansas City, MO, USA). Weir's[5] formula was used for calculating RMR.

Body composition. The subjects were weighed to the nearest 0.1 kg every week on a balance (ED-60-T; Berkel, Ridderkerk, The Netherlands) before dinner, while wearing underwear. Body composition, i.e. fat mass and fat-free mass (FFM), was estimated from the three-compartment model of Siri[6] which combines body density with total body water. Body density was measured using the hydrostatic weighing technique of Brozek et al.[7] Underwater weight was determined to the nearest 0.1 kg with a balance (SK; Berkel, Ridderkerk, Netherlands) while the residual lung volume was determined simultaneously by helium dilution and a spirometer (Volutest; Mijnhardt, Bunnik, The Netherlands). Total body water was determined by deuterium dilution.

Plasma malondialdehyde (MDA). For the analysis of MDA blood was collected in EDTA-containing tubes. Plasma was stored under helium at –80°C until analysis. MDA was analysed fluorometrically (Perkin-Elmer spectrophotometer 204-A, Gouda, The Netherlands) after formation of an adduct with thiobarbituric acid (TBA) as reported by Hendriks and Assman.[8]

Low-density lipoprotein resistance of ex-vivo copper-mediated oxidation (LDL-ox) was analysed according to the method of Princen et al.[9] The lag-time (min) was used as a measure of LDL-ox.

8-Hydroxydeoxyguanosine (8OHdG) in lymphocytes. Lymphocytes were isolated using Ficoll. From these lymphocytes DNA was isolated. The number of 8OHdG adducts was measured by HPLC with electrochemical detection, essentially according Richter et al.,[10] and was expressed mol 8OHdg per 10^5 mol deoxyguanosine. Analysis of lymphocyte 8OhdG was completed in 19 subjects at the start of the intervention (ER group n = 13; control group n = 6), and in 22 subjects at the end of the intervention (ER group n = 15, control group n = 7).

Urinary 8OHdG. 24-hour urine samples were collected at the end of the run-in period and at the end of the experimental period and stored at –20°C until analysis of 8-OHdG by HPLC with electrochemical detection.[11] The second urine collection was not completed in one subject from the ER group.

For the analysis of *catalase, GSH-Px and SOD in erythrocytes,* heparinized blood was collected. Erythrocytes were washed three times and stored at –80°C until analysis.

Catalase activity (EC 1.11.1.6) was measured by monitoring substrate (H_2O_2) disappearance spectrophotometrically (LKB, Cambridge, UK) at 240 nm according to the method of Aebi.[12]

GSH-Px activity ((EC 1.11.1.9) was measured according to a 'FLAIR-standardize method' (Belsten and Wright, unpublished). This FLAIR assay is based on Paglia an Valentine's method,[13] including an enzyme stabilization step and using t-buty hydroperoxide rather than hydrogen peroxide.

SOD activity (EC 1.15.1.1) was measured spectrophotometrically (LKB, Cam bridge, UK) using the RANSOD kit (Randox laboratories, Ireland) according to the kit' protocol.

Total vitamin C. Vitamin C concentration in whole blood was measured by HPL(with fluorometric detection[14] immediately after blood sampling (between-assa variability: 5%).

Vitamin E, vitamin A and β-carotene. Heparinized blood was collected. Plasma wa separated immediately after collection by centrifugation (10 min, 2000g) and stored a -80°C until analysis. Vitamin E, vitamin A and β-carotene were analysed by HPLC a described by van Vliet et al.[16]

Total cholesterol. For the analysis of total cholesterol concentration a commerciall available kit was used (Boehringer Mannheim Diagnostica, Amsterdam, Th Netherlands).

Hemoglobin (Hb) concentration was determined by using a semi-automati computer equipped hematology analyser (Sysmex K1000, Japan; DA1000, Japan).

Near the end of the experimental period (after 10 weeks of moderate energ restriction) after an overnight fast, blood was collected by venapuncture into heparinize tubes. Lymphocyte cultures were set up using whole blood and phytohaemaglutini stimulation for the assessment of a variety of cytogenetic biomarkers by routin methods: 1) sister chromatid exchanges (SCE),[16,17]; 2) chromosomal aberrations[16,17] 3) micronuclei in binucleated cells (cytokinesis block method[18]).

Statistics:

BMDP statistical software (Los Angeles, CA, USA; version 1990 VAX/VMS) was use to detect changes within and between the groups, and to calculate correlations betwee variables. Changes within the groups were tested for significance with the paire Student's t-test. Differences in changes between the two groups were tested with th unpaired Student's t-test. Relationship between two variables was calculated wit Pearson linear correlations. P-values were considered statistically significant at $P < 0.05$

RESULTS

Table 7.1 presents the physiological characteristics, including body weight and RMR before and after the intervention as well as the change (Δ) that had occurred at the end of the intervention. As expected, there was a considerable weight loss in the ER group, which was significantly greater than the relatively small weight loss in the control group. At the end of the intervention period subjects were still losing weight, and there was no tendency to stabilize. As a consequence of the weight loss, BMI decreased significantly in the ER group. RMR significantly decreased in both groups. RMR tended (p = 0.06) to decrease more in the ER group than in the control group. Even after adjusting for body composition, RMR still significantly decreased in both groups, suggesting an increase in metabolic efficiency in subjects in negative energy balance.

The effects of a moderately energy-restricted diet on indicators of oxidative stress and anti-oxidative capacity are summarized in Table 7.2. No effects could be demonstrated for any of the indicators of oxidative stress (MDA, LDL-ox and 8OHdG) measured. 8OHdG was measured in both lymphocytes and urine. Lymphocyte 8OHdG is considered to reflect the balance between damage and repair at the time of sampling, while urinary 8OHdG is interpretated as the rate of oxidative DNA modification. Neither indicator of oxidative DNA modification was affected significantly by ER. However, the change in 8OHdG excretion, i.e. the change in the rate of rate of oxidative DNA modification, correlated positively with the change in RMR (r = 0.516, P = 0.017, n = 21) when both indicators were expressed per kg fat-free mass (FFM). Of the free-radical-scavenging enzymes measured, catalase significantly decreased in both groups, with no difference between groups. The activities of the two other free radical scavenging enzymes, GSH-Px and SOD, did not change. Of the antioxidant vitamins analysed, vitamin C concentrations increased significantly in the ER group, but not in the control group. The change in whole blood vitamin C concentration correlated with the change in 8OHdG excretion when all subjects were included in the analysis (r = 0.478, P = 0.021) (Figure 7.1). Plasma vitamin E concentration decreased in the ER group. However, when expressed relative to plasma total cholesterol concentration this decrease was not significant. No changes were observed in plasma vitamin A concentrations. Beta-carotene concentration increased significantly in the ER group, but this increase was not significantly different from the nonsignificant increase in the control group.

No differences between the two groups were observed for any of the indicators of genotoxicity measured after 10 weeks of moderate energy restriction only (Table 7.3).

DISCUSSION

One of the hypothesis that has been put forward to explain the ageing process is th｜ ageing is related to a disregulation in the balance between prooxidants and antioxidar｜ leading to oxidative stress. The large body of literature on animal studies indicates th｜ 1) the levels of anti-oxidant defence are positively correlated with species life spa｜ 2) the rate of production of free radicals correlates inversely with species life spa｜ 3) anti-oxidant defence declines with increasing age, 4) the rate of production of fr｜ radicals increases with age and that, as a result, 5) oxidative damage increases wi｜ age.[19] However, results are not always comparable because of differences in stu｜ protocol and type of experiment (matrix, type of marker, species, sex, age groups etc｜ Nevertheless, results obtained in lifelong studies in animals strongly suggest that t｜ maintenance of an appropriate antioxidant/prooxidant balance does have an importa｜ role in maintaining health in ageing.[20] One of the best known age-related signs of lip｜ peroxidation in both animals and humans is an accumulation of the lipoidal fluoresce｜ called lipofuscin or age pigment. Lipofuscin is formed in non-dividing cells, such｜ neurons and skeletal and cardiac muscle cells, from the auto-oxidation of lipids, whi｜ involves free-radical chain reactions.[21] An age-related increase in another lip｜ peroxidation product, MDA, has also been observed in human subjects aged between｜ and 80 years,[22] and when comparing young people (21-43 years) with elde｜ (> 65 years).[23] In addition, lower platelet vitamin E levels[23] and lower platelet GSH-｜ activities[23] were found in the elderly humans. Niwa et al.[24] reported that the inducibil｜ of lymphocyte SOD in healthy subjects decreases with age. Moreover, low inducibil｜ at 67-73 years appeared to be predictive of malignancy or fatal cardiovascular events f｜ the next 5 years. Recently, Orr and Sohal[25] reported that simultaneous overexpression｜ SOD and catalase in Drosophila melanogaster resulted in a one-third extention｜

lifespan and a longer mortality rate doubling time, which supports the free radical hypothesis of ageing.

Thus, in both animals and humans an age-related increase in lipid peroxidation is apparent. Two years ER in rodents seems to prevent this age-related increase in lipid peroxide levels and decrease in anti-oxidant defence in rodents.[26] ER might therefore have a similar beneficial effect in humans.

The aim of our intervention was to study the short-term effects of moderate energy restriction on indicators of oxidative stress and antioxidative capacity as well as on resting metabolic rate in humans. Since, to our knowledge, no previous studies have addressed this question, this appears to be the first attempt to study the relevance of findings from animal studies to human beings. An interesting long-term experimeny involving ER in humans is Biosphere 2. The diet of the eight subjects in this ecosystem is low in energy (7,500 kJ/day) and fat (10% of energy intake). Body weight and clinical chemistry data have been published[27] but not data concerning prooxidant/antioxidant balance.

Our results are hard to compare with data obtained from animals since data on the effects of short-term ER in animals are scarce and unequivocal: Yu[3] found that the anti-lipid peroxidative action of ER (40% of ad libitum), initiated at 6 weeks of age, was discernable after six months of ER as indicated by suppressed MDA formation, while Rao et al.[28] did not demonstrate an effect of ER (60% of ad libitum), also initiated at 6 weeks of age, on MDA formation after four months. Although these studies are classified as short-term, the duration of ER is approximately ¼ of the life span of the rodent, which might compare roughly to 15 to 20 years in humans. Another difficulty in comparing our data with data from animal studies is the age of the subjects used. Althoug ER initiated in adult rodents extends longevity,[29] it remains to be established whether ER imposed in full-grown animals acts through similar physiological mechanisms as when imposed soon after weaning.

Considerably more data are available concerning the effects of long term (24 months) ER in animal models. Yu[3] noted that MDA generation in freely fed rats increased with age. The anti-lipid peroxidative action of 60% ER was demonstrated by suppressed MDA formation. Rao et al.[28] observed that the 40% ER-induced retardation of the age-dependent increase in MDA levels was apparent at 12 months of age. With respect to ex-vivo LDL oxidizibility, to our knowledge, no studies have reported the effects of ER on LDL-oxidizibility. Oxidative DNA damage as measured by 8OHdG was attenuated by 40% ER in livers of 24-month old rats.[29] The prodects of DNA damage (including non-oxidative DNA damage) accumulate with age in mice[30] and may therefore contribute to the ageing process. We therefore hypothesized that the beneficial

effects of ER might be reflected in fewer cytogenetic biomarkers for genotoxicity Although, cytogenetic biomarkers were not measured at the start of the study there is n reason to assume that they differed between the groups at the start of the intervention Pieri et al.[31] studied antioxidant enzymes activities in erythrocytes from youn (6 months), old (24 months) and energy restricted (fed every other day) old rats an found an age-associated decrease in activities of catalase and GSH-Px, which wa prevented by ER. Most of the data concerning ER and ageing are generated by lifelon animal studies. Therefore, it was uncertain whether we could expect a beneficial effe of ER on the indicators presented in this paper. In addition, a complicating factor comparing human to animal data is that most of the evidence in animal studies is base upon findings obtained from unaccessible organ tissues, especially liver. Studies humans are limited with respect to the substrates for analysis since only blood and urin samples are readily available.

Figure 7.1. Relationship between the change in the rate of oxidative DNA damage (8OHdG excretio and the change in whole blood vitamin C concentration after 10 weeks of consuming weight maintaining diet or a moderately energy restricted diet.

Ten days of ER (5,000 kJ/day) in one human subject has been shown to decrease urinary 8OHdG excretion.[32] In our study we found no support for our hypothesis, i.e. no reduction in measures of lipid peroxidation, anti-oxidative capacity, DNA modification or genotoxicity were observed after moderate ER for ten weeks. No effects were observed on plasma anti-oxidant vitamins, except for vitamin C concentrations which increased in the ER group. As vitamin C intake did not differ between groups (see 'experimental design' section), differences in intake cannot explain the increase in whole blood vitamin C concentrations.

Surprisingly, there was a positive correlation between the change in the rate of oxidative DNA damage, 8OHdG excretion, and the change in whole blood vitamin C concentrations when all subjects were considered. Since vitamin C is a free radical scavenger, we expected a negative correlation, i.e. an increase in vitamin C level should reduce the rate of oxidative DNA damage. The explanation, presumably, is related to an interplay between vitamin C and other antioxidants. An additional factor could be a changed distribution between intra- and extracellular vitamin C. Whether there is a relationship between oxidative DNA damage and vitamin C concentration in the habitual, or in the vitamin C supplemented state, and whether this correlation is physiologically relevant, is presently unknown.

In the ER group the PUFA/SFA ratio (P/S ratio) appeared to be higher in the food supplied (0.82 ± 0.04 in the control group; 0.57 ± 0.03 in the ER group) than in the subjects' habitual diet (0.39 ± 0.09 in the control group; 0.42 ± 0.10 in the ER group). The increase in P/S ratio (0.43 ± 0.12 in the control group; 0.15 ± 0.10 in the ER group) could have strengthened a potential effect since this increase was most apparent in the control group. However, since no effects could be demonstrated the change in dietary fatty acid profile was of no apparent importance.

Since free radicals are thought to be derived from O_2 during oxidative metabolism, lower metabolic rate may partly explain the beneficial effects of ER. Although the rate of oxidative DNA damage as evaluated by a paired t-test did not change after moderate energy restriction, we observed that the change in RMR per kg fat-free mass (FFM) correlated with the change in 8OHdG excretion per kg FFM. Detailed analysis of this finding will be published elsewhere.[33] The subjects did not reach a new energy balance because they were still losing weight at the end of the experimental period. It is not certain whether RMR would still be lower after a new weight equilibrium had been reached. It has been reported that obese subjects have a higher RMR/kg FFM[34] whereas girls suffering from anorexia nervosa have a lower RMR/kg FFM[35] than normal-weight subjects. Despite the fact that we studied lean instead of obese or anorectic subjects and moderate energy restriction in stead of semi-starvation, on the basis of these reports it

could be expected that RMR/kg FFM would remain lower in the ER subjects studied i
this experiment. Several explanations for not finding any changes in the indicator
measured can be suggested: 1) since humans have a low metabolic rate they may suffe
relatively less from damage due to free radicals, therefore, they might benefit less fror
ER than species with a high metabolic rate; 2) the small ranges of the variable
measured may be the cause of not finding any correlations between variables, 3) th
period studied might have been too short. However, under controlled conditions like i
this study, 10 weeks is the longest period one can expect a subject to participate ir
4) antioxidative capacity might be rather stable in the age category used in this stud
and 5) as already mentioned, another reason for not finding changes in the indicators c
oxidative stress and antioxidative capacity might be the tissue used. Finding no effec
on a peripheral level does not exclude changes on a cellular level.

The imposed level of ER (20% of reported intake) was probably too high to be accep
able for the long term because the subjects kept losing weight and showed no tendenc
to stabilize. In this study we aimed at 20% ER, but the real imposed ER may have bee
higher because of underreporting of habitual intake (as indicated by weight loss in th
control group). A milder level of energy restriction would probably be more feasible bt
whether this level of ER beneficially afects the ageing process in humans remains to t
studied.

To summarize, in this study ER did not affect indicators of antioxidative capacit
oxidative stress or genotoxicity in humans. A correlation between the change :
RMR/kg FFM and the change in urinary 8OHdG/kg FFM was found. However, sin
subjects were not stabilized at a new energy balance no conclusions can be drawn wi
respect to the long-term effect. Not finding an effect on the variables measured in th
study does not necessarily mean that ER does not affect oxidative stress and/or tl
ageing process in humans. More studies, utilizing better markers for oxidative stress th;
presently available, are needed before a definitive conclusion can be drawn.

ABSTRACT

The aim of this paper is to present the background, study design and outcome of the magnitude of experimental manipulation of a long-term multicentre study on health effects of reduced fat products. The design of this study is a randomized semi-controlled parallel comparison trial of six months, preceded by a one-month adaptation period, in which healthy non-obese male and female volunteers, 19-55 yr, participated. The study was performed by three research centres and one coordinating centre. 241 volunteers were recruited from the general population. 220 completed the study, 117 of the reduced fat group and 103 of the control group. The subjects consumed either reduced fat or full-fat products, clearly labelled as such, in a free-living situation, obtained from a realistic supermarket at the research centre. The magnitude of the experimental manipulation was that the reduced fat group consumed on average 46% less fat from the experimental products than the control group. Consumption of the experimental products remained stable throughout the study period in the control group and increased significantly in the reduced fat group. It has been concluded that the setup of this study was feasible for such a long-term semi-controlled trial, that the adherence to the experimental products was excellent throughout the study, and that the magnitude of experimental manipulation appeared to be what we had planned.

INTRODUCTION

An excessive consumption of total fat and saturated fat increases the risk of coronary hea[r]t diseases, obesity, some types of cancer, and possibly gall bladder disease.[1] Therefore, man[y] countries have advised individuals to reduce their total fat intake to between 30 to 3[5] percent of total daily energy intake and saturated fat intake at or below 10% of total energ[y] intake.[2,3] Results of recent food consumption surveys in Europe and North America hav[e] shown however that average fat intake still exceeds these recommendations.[4-6] Besides, th[e] prevalence of overweight and obesity has remained stable or has even increased in sever[al] western countries over the past decades.[7-9] These data indicate that dietary recommendation[s] have not been successfully implemented by the consumer, in spite of the growth i[n] consumer awareness of health and nutritional issues over the last decades and the increas[e] in availability of reduced fat products, at least in North America and the northwestern pa[rt] of Europe.[10]

One of the reasons for these findings seems to be that many people underestimate the[ir] actual fat intake.[11] Other reasons might be that reduced fat products are less palatable[12] [or] that intake compensation for the decreased fat and energy intake occurs after consumptio[n] of reduced fat products. A number of studies have investigated the effectiveness of reduce[d] fat products to decrease total energy and fat intake using different study designs.[13-27] In a[ll] of the performed studies, irrespective of their design and duration, macronutrient specifi[c] compensation was negligible. If reduced fat products were offered, fat consumption did n[ot] specifically increase during the ad libitum food consumption periods and total daily f[at] intake decreased in comparison with the consumption of high-fat products. No consensu[s] exists however about the effect of reduced fat products on total daily energy intake althoug[h] most studies found a decrease in total energy intake.[13-15,18,19,21-26]

However, these studies have invariably included not very large numbers of subject[s] (minimum: n = 5[19] to maximum: n = 47[26]), studied partly under laboratory conditions an[d] over a period of time usually no longer than 11 weeks (e.g.[22]). Besides, the impact [of] knowledge about the nature of the experimental manipulation has not always been take[n] into account in the previous studies. To obtain results with a high ecological validity, thi[s] aspect should be taken into account because in everyday life consumers buy products tha[t] are overtly marketed as reduced fat alternatives of traditional products. Eating behaviou[r] may be differently affected when information about the fat content of a consumed produc[t] is present.[28] Therefore, we have executed a multicentre six-months study in which a larg[e] group of volunteers had free access to both reduced fat commercially available products i[n] the laboratory as well as to products obtained from regular shops. We here report th[e] magnitude of the experimental manipulation we achieved in this study under realistic, semi[-] controlled circumstances.

SUBJECTS AND METHODS

Subjects

The protocol of the study was approved by the Research Ethics Committees of each participating research centre. Subjects gave their written informed consent prior to participation. Volunteers who completed the study received a financial reward.

Volunteers were recruited amongst inhabitants of the areas where each research centre is located. Each research centre recruited and selected their own volunteers. Eligible adult volunteers (19-55 yr), were healthy as assessed by a medical investigation (serum cholesterol level $\leq$ 8 mmol/L) and not obese (QI 21-28 kg/m^2 at age 19-35 yr and QI 24-30 kg/m^2 at age 36-55 yr). They did not use a medically prescribed or slimming diet and had been weight-stable for at least one month prior to the start of the study. Exclusion criteria were intensive exercise (> 7 hrs/week), excessive alcohol intake (> 21 vs 28 units/week for females vs males) and for females: pregnancy or lactation. These criteria were chosen because we wanted to study the health effects of consumption of reduced fat products in a population of healthy normal- to slightly over-weight people in a stable physical condition, having no or moderate exercise habits and not drinking too heavily. We chose different ranges of eligible Quetelet Indexes for the age groups under and over 36 years because it has been shown that the average Quetelet Index of populations increases with age.[4] Blood and urine samples were taken for analysis of clinical parameters to evaluate the state of health of the volunteers. These parameters were also assessed at the end of the study. Fasting body weight was assessed of the subjects in underwear and after voiding. Body height was measured and sociodemographic characteristics and eating behaviour characteristics were assessed by questionnaires. Eating behaviour characteristics were assessed with a Dutch translation[29] of the Three Factor Eating.[30]

Half of the volunteers of each research centre had to be younger than 36 yr and the other half had to be 36 yr or older. This criterium was applied to obtain a comparable age distribution among the different research centres.

241 volunteers were selected; 59 males and 61 females were assigned to the control group and 60 males and 61 females to the reduced fat group.

Study design

The study was a multicentre parallel comparison trial of six months. 241 non-obese volunteers received either reduced fat products (reduced fat group) or full-fat products (control group) and the products were clearly labelled as such. Two months before the start of the study, a one month adaptation period was executed to optimize the experimental procedures.

Four research centres participated in this MSFAT study (Multicentre Study on FAT

reduction). Three centres, the Agricultural University of Wageningen, the University
Limburg in Maastricht and TNO Nutrition and Food Research Institute in Zeist, ea
selected 80 or 81 volunteers. The fourth research centre, Unilever Research Laboratoriu
in Vlaardingen, was responsible for coordination of the study and for carrying out some
the measurements.

In each test facility, volunteers were randomized over the two study groups, ensuri
an equal distribution over the groups of both sexes, eating behaviour characteristi
(restrained or unrestrained eater) and type of household (single, two-person or fami
household), as far as possible. Both groups were matched for mean age and Quetelet Inde

Power of the study
Power calculations indicated that, taking into account a dropout rate of 20%, 120 voluntee
per treatment group in this design would provide sufficient power to detect a significa
difference between the reduced fat and control group in e.g. change in fat intake
3.4 en%. The target of the design was to obtain a reduction in fat intake in the reduced f
group of 40 to 30-35 en% compared to the control group.

Hypothetical calculations showed that this aim would be achieved if the reduced f
products would provide 50% less fat compared to the full-fat products and if in the contr
group about 70% of the total fat intake would be derived from the experimental produc

Experimental foods
Based on manufacturer's food composition data and results of sensory tests, a selection w
made of the pairs of products of fat-reduced and control products which agreed most
nutrient composition except for fat, had the best sensory similarity and were evaluated
acceptable for regular consumption during six months. Appendix I shows the pairs
products which were included in the study as experimental products and their macronutrie
composition. The experimental products were identical to commercially available foods a
labelled as branded products. Only the cakes and cookies were not commercially availab
but manufactured specifically for the experiment.

The macronutrient and vitamin E content, as well as the fatty acid composition of t
products were analyzed at the end of the study in one of the research centres. Macronutrie
content and fatty acid composition were analyzed in duplicate products or in a homogeniz
mixture of duplicate products. Fat content was assessed by direct extraction after free
drying, carbohydrate content was assessed by spectophotometry after extraction wi
perchloric acid and Antron coloring, protein content was assessed by Kjeldahl destructi
and fatty acid composition was determined by gaschromotography. Vitamin E was analyz
by straight phase HPLC in duplicate in a selection of experimental products which we
expected to contain a high amount of vitamin E, based on food composition data.[31] T

pizza Picante and Bellisima appeared to be the only pair of products which were classified wrongly, due to a mistake in the food composition data. These products were available throughout the study because the analyses were executed at the end of the study. The pairs of reduced fat and control products differed mainly in fat content as shown in Appendix I. The average difference in fat content was 52%.

Availability of experimental foods

A small supermarket, resembling a regular small supermarket as much as possible, was installed at each research centre. The supermarkets were open during 6 to 7 hrs per week, divided over three occasions and in principle subjects came once a week. If a volunteer could not consume the experimental products during a holiday and if this lasted longer than one week, the experimental period was extended for this particular volunteer by the duration of the holiday. This extension was maximally one month.

Volunteers were free to take as many products as they wanted. They were also allowed to buy foods in regular shops. In fact this was essential since a number of products (e.g. bread, cereals, fruit, vegetables, meat, beverages) were not available.

Consumption of the experimental products was registered by a computer programme. The products taken from the supermarket were registered with a barcode reader and during the next visit volunteers reported how much was left in stock at home and how much had not been consumed but thrown away. Volunteers' consumption of the experimental products could be calculated with this information, so that the subjects did not have to register their consumption every day.

Volunteers in the control group had to consume at least 35 g fat/day from the experimental products. The aim was to maintain a 50% difference in fat intake from the experimental products between the treatment groups. Therefore, in the reduced fat group, volunteers had to consume at least so many reduced fat products that the hypothetical difference in fat content between these consumed reduced fat products and the full-fat counterparts exceeded 17.5 g fat/day. For practical reasons, the minimum amount volunteers had to consume was independent of their energy requirements. Volunteers who failed to meet this criterium, i.e. were actually not taking part in the experiment, were told so by the investigator. If a volunteer did not respond and consumed less than the minimum amount during four consecutive weeks, participation was stopped, unless good reasons were given. This instruction may have interfered slightly with the free-living concept of the study. However, it was considered essential to have some form of control over the intake of the experimental products in order to successfully complete the study.

Measurement of total food intake

Total food intake was assessed before the adaptation period, after 2-4 weeks, 3 months and

at the end of the main study period. Volunteers recorded their food intake during tw weekdays and one weekend day, estimating quantities in household measures.[32] Eac particular volunteer stuck to the same days of the week and weekend during each of tł four measurement periods. Macronutrient and vitamin E intake were calculated using tł Dutch food composition table[31] and data of our own analyses of the experimental product:

At the time of the baseline measurement of food consumption, before the start of tł adaptation period, volunteers were still unaware of which treatment they would receive avoid a possible effect of this knowledge on their habitual food intake before the start the study.

Statistical analyses

Significance of differences in descriptive characteristics and fat consumption from tł experimental products between the treatment groups, within subgroups of volunteers, w assessed by Student's t-test for continuous variables and by Fisher Exact test for numeric variables. Significance of differences within treatment groups, between subgroups volunteers, was assessed by Student's t-test for the subgroups divided according to gend and age, and Tukey's studentized range test was used to detect pairwise differences betwee the subgroups of research centres. The interaction between treatment group and researc centre was assessed by analysis of variance to investigate a difference in treatment effe on the fat consumption from experimental products between the research centre Significance of differences between different time points in fat consumption fro experimental products, within one treatment group and subgroup, was assessed with Tukey studentized range test.

SAS computer software was used for all statistical calculations.[33] All comparisons we made at the two-sided 0.05 significance level.

Data monitoring

Standardized information material and selection procedures were used during recruitme of the volunteers. Procedures for general measurements, e.g. haematological and uri investigations, discussions of food consumption diaries with the volunteers, were describ in standard operating procedures. Besides, the responsible investigators of each resear centre attended a training session on the procedures of food consumption diaries minimize observer bias. Blood chemistry investigations and processing of the fo consumption data were performed centrally.

The coordinating research centre visited the test facilities regularly to make sure tł differences in study procedures were minimized. Besides, regular meetings between investigators were organized to discuss how the study proceeded.

RESULTS

Volunteers

A total of 117 volunteers of the reduced fat group and 103 volunteers in the control group completed the study according to the protocol. In the control group, four volunteers withdrew immediately after randomization because they preferred the reduced fat group and one volunteer because she disliked the taste of the control products. Three volunteers withdrew because of pregnancy, nine because of changed personal circumstances (e.g. medical reasons, removal, illness of partner) and four volunteers were asked to quit participation because of non-compliance. These 21 volunteers who dropped out of the study, did no differ in mean descriptive characteristics and food consumption pattern from the volunteers who completed the study, as shown in Table 8.1.

Table 8.1. Mean ± SD baseline values of descriptive characteristics, socio-demograghic characteristics and food consumption of volunteers who dropped out before the the end of the study and volunteers who completed the study.

[a,b] Means in the same row with different superscripts are significantly different ($P<0.05$)
[1,2] Means at a certain time point within the treatment groups are significantly different between the subgroups with different superscripts ($P < 0.05$).
Note: means of the reduced-fat group are significantly different from the control group at each time point, within each subgroup ($P < 0.05$).
Note: means within the treatment groups are significantly different between male and females at each time point ($P < 0.05$).

Tables 8.2-8.4 show the descriptive and sociodemographic characteristics and the averaş energy and fat intake before the start of the study of the volunteers who completed tl study as per protocol. No significant differences were found in baseline characteristi between the treatment groups within any of the subgroups, except for the differences in f intake between the reduced fat and control group in the subgroup of volunteers participatir in the Agricultural University of Wageningen (respectively 33.4 en% and 36.2 en% P = 0.04). All values of the clinical parameters, as assessed before as well as after tl study, were within the normal ranges. This indicates that healthy subjects were selected ar that they were still in good health after completion of the study.

The study was extended for 38 volunteers by two to four weeks because the: volunteers had been on holiday or had been ill for one or more weeks during tl experimental period.

Obtained magnitude of experimental manipulation

Table 8.5 shows the consumption of experimental products, expressed as the daily amou of fat intake from the experimental products, calculated from the data of the foc consumption diaries. The remainder of the fat intake came from non-experimental product bought in regular shops.

Volunteers in the reduced fat group consumed significantly less fat from the reduce fat products than the amount of fat volunteers in the control group consumed from the ful fat products. In both treatment groups, at each time point, males were found to consum significantly more experimental products than females. At each time point, volunteers in tl reduced fat group who participated in the TNO Nutrition and Food Research Institu consumed significantly more from the experimental products than the volunteers in tl reduced fat group of the other two research centres. No effect was found however from tl type of research centre on the outcome of the difference between the treatment groups fat intake derived from the experimental products. Significant differences between the aş groups were found only in the control group, six months after the start of the stud Volunteers in the older age group (≥ 36 yr) consumed significantly more from tl experimental products than the younger volunteers.

The amount of fat intake from the experimental products in the entire control grou remained stable throughout the study period and increased significantly in the reduced f group between three and six months after the start of the study. This significant increas was not present in all subgroups of volunteers of the reduced fat group and in some of tl subgroups, a significant increase in fat intake from the experimental products was found the control group.

The magnitude of the experimental manipulation, i.e. the average difference in fat consumption from the experimental products between the entire reduced fat and control group, calculated over the whole study period, was 46%.

DISCUSSION

In this six-months, semi-controlled study, we achieved an experimental manipulation of an average reduction of 46% of fat intake from the experimental products in the reduced fat group compared to the control group. The consumption of experimental products did not decrease during the time course of the experiment. These findings indicate that compliance to the treatment was good and that the magnitude of the experimental manipulation we had planned, i.e. 50% reduction in fat intake from the experimental products in the reduced fat group, has been achieved. The volunteers consumed on average ± 70 g fat/day from the full-fat products. This would be 70% of their total daily fat intake, if total fat intake in this group has remained the same as before the start of the study (± 100 g fat/day). Also this contribution of the experimental products to the total diet was the size we had aimed at.

The difference we found between males and females in consumption of the experimental products could be expected because of the difference in average energy requirements between males and females. We also found a difference in consumption between the young and old age groups. This difference was however not expected because the older volunteers were found to consume less energy at baseline than the younger volunteers. Although it was only found at the end of the study and only in the control group, this points to a difference in compliance to the experimental products between the age groups. The older volunteers may have felt more affected to the experiment or it may have been more easy for them to introduce the experimental products in their diet.

A multicentre approach was chosen because of the broader range of parameters which could be investigated with the different expertises and the geographical spread over the country. One of the disadvantages of a multicentre approach is the possibility that between-laboratory variation occurs in experimental procedures. Despite the strict standardization, we did find a difference in consumption of experimental products between the research centres. This difference can not be explained by a difference in average total energy requirements between the subgroups of volunteers, because we did not find a difference in baseline daily energy intake between the different research centres. The difference may therefore be due to a difference in interaction between the investigators and the volunteers. No interaction was found between the type of research centre and the treatment effect on the fat intake from experimental products and thus the magnitude of the experimental manipulation was not different between the research centres. The treatment effect on total

daily fat intake may therefore not be affected by the type of research centre.

Average daily energy intake at baseline was comparable to what has been fou during the Dutch food consumption survey[6] in males and females of similar age grou (22-50 yr). Average percentage of energy derived from fat in our volunteers was howev somewhat lower than the 37 en% found in the Dutch food consumption survey. During t baseline measurement the weather was unusually hot in The Netherlands. This may ha affected the dietary intake during those days. Our target was that the control group wou consume about 40 en% of fat and that the reduced fat group would reduce their fat inta to on average 30-35 en%. As our population was used to consume less fat than 40 en% fat, an increase in fat intake may be found in the control group instead of a stable f consumption, due to an increase in consumption of full-fat products. On the other han only a small reduction in fat intake can be expected in the reduced fat group. This w however not affect our conclusions about a possible positive effect of reduced fat produc on energy and fat intake. Previous studies using a parallel design have also drav conclusions about differences in treatment effects while both treatment groups showed change in the investigated parameters.[34,35]

In conclusion, the compliance to the experimental products in this six-months ser controlled trial did not decrease during the time course of the experiment and the magnitu of the experimental manipulation we aimed at was achieved. We therefore believe we ha completed the long-term, realistic trial necessary to answer the question wheth consumption of reduced fat products is an effective tool to decrease total fat intake and improve human health.

ABSTRACT

A high fat intake has been associated with the high prevalence of coronary heart disease (CHD) in most western countries. Consumption of reduced fat products might reduce the fat intake and beneficially affect markers of CHD risk. Therefore, the effects of 6 months realistic consumption of reduced fat products on energy and fat intake, concentrations of Factor VII, PAI-1 antigen and fibrinogen as well as tPA activity was investigated. In addition, an oral glucose tolerance test was performed to study the effects on insulin sensitivity, in relation to haemostatic factors. Participants (n = 76) were healthy, non-obese men and women. The reduced fat group (n = 40) showed a significantly lower energy intake as well as a lower percentage energy derived from fat than the control group (n = 36), who received the full fat equivalents. However, this did not result in differences in the haemostatic parameters measured, or in altered insulin sensitivity. It has been concluded that consumption of reduced fat products does not decrease, nor increase, the CHD risk through improvement of the risk markers Factor VII, fibrinogen, PAI-1 antigen, tPA activity and insulin sensitivity in healthy non-obese subjects.

INTRODUCTION

A high fat consumption, especially when rich in saturated fat, has, besides smoking
been targeted as an important enemy of good health. The high prevalence of coronar
heart disease (CHD) in most western countries has been associated with a high fa
intake, i.e. it is often higher than the recommended 30-35% of total energy intake. I
recent prospective epidemiological studies, various haemostatic risk indicators for CHI
have been identified. In the Northwick Park Heart Study both elevations of fibrinoge
and of Factor VIIc were risk indicators.[1] Fibrinogen has been been established now as
prominent risk indicator in several other prospective studies.[2-9] Factor VIIc obtained les
support in prospective studies: Another prospective study could not confirm the finding
in the The Nortwick Park Heart Study.[5] In several cross-sectional studies, however, post
myocardial infarction patients had significantly elevated levels of Factor VII compare
to controls.[10-12] Also, recently the blood fibrinolytic activity,[13,14] determined mainly b
tissue-type plasminogen activator (t-PA) and its inhibitor (PAI-1), has been recognize
as risk indicators.[15] Specific studies showed a prospective value of elevate
PAI-activity,[16] reduced t-PA activity[17,18] and elevated t-PA antigen.[9,19-22] Studies of Juha
Vague[23] indicated that elevation of PAI-1 and reduction of blood fibrinolytic activity ar
related to insulin resistance. Potter van Loon et al.[24] atribute this abnormality to a clos
relation to insulin resistance.

The growing public concern about the adverse effects of a high fat intake has le
to an increased availability of 'reduced-fat' products. Consumption of reduced-fa
products might be a convenient way to reduce the fat intake and might consequentl
reduce the CHD risk.

The present study was performed in order to investigate whether a realisti
consumption of reduced-fat products can alter dietary fat intake as well as markers o
cardiovascular risk, including fibrinolytic factors and insulin sensitivity.

In this paper we present the effects of 6-month consumption of reduced-fa
products on energy and fat intake, PAI-1 antigen, tPA activity, fibrinogen and Factor VI
concentration in 76 healthy non-obese subjects. Moreover, an oral glucose tolerance tes
was performed to assess the effects of reduced fat products on insulin sensitivity, i
relation to haemostatic factors. The reduced-fat products were provided through
realistic shop in order to mimic a 'free living' situation.

SUBJECTS AND METHODS

Subjects

Eighty apparently healthy subjects (40 men, 40 women) started as a participant in the study. They were selected from responders to advertisements in regional newspapers. Subjects were aged between 20 and 55 yr. Those aged between 20 and 35 yr had a body mass index (BMI) between 20 and 28 kg/m², and those aged between 35 and 55 yr had a BMI between 24 and 30 kg/m². All subjects were medically screened by a physician. Routine clinical chemistry, blood pressure and lipid profile had to be within normal ranges. Exclusion criteria were: following a medically prescribed diet or slimming diet; being pregnant or wishing to become pregnant during the experiment; weight loss or gain > 2 kg/month 1 month before prestudy examination; and sporting activities of more than 7 hrs/week. Subjects were randomly assigned to either the reduced-fat group or the control group which received the full-fat equivalents. The groups were stratified according to gender, age, BMI, eating behaviour characteristics and type of household. Four females from the control group withdrew from the study because one disliked the taste of the products, one got pregnant, and two because of changed personal circumstances, so that 36 subjects in the control group and 40 in the reduced-fat group finished the study. The study protocol was approved by the Institute's Medical Ethical Committee and the participants signed an informed consent form.

Study design

The study was part of a multicentre study, the MSFAT-study, on the long-term health effects of realistic consumption of reduced-fat products in healthy non-obese volunteers. The design was a randomized 6 month parallel comparison trial which has been described extensively elsewhere (Chapter 8).[25] In short, four Dutch research centres participated in the study. One centre was responsible for coordination of the study, the other three centres selected each about 80 volunteers. A realistic shop was installed in these three centres. Two months before the start of the study, an one month adaptation period was executed to optimize the experimental procedures and to get the volunteers used to these procedures. Volunteers were free to take as many of the reduced fat products or their full fat equivalents (e.g. spreads, dressings, frozen meals, cheeses, meat products, non-dairy creams, biscuits, snacks etc.) as they wanted. They were also free to buy non-experimental products such as bread and vegetables in regular shops. In the three centres food intake was assessed before the adaptation period, after 2 weeks, 3 months and at the end of the study by 3-day food consumption diaries, estimating quantities in household measures. Body weight was assessed before, after two months, four months and at the end of the study. Next to the general measurements research

centre-specific measurements were performed. In the subjects participating at ou
Institute fibrinolytic factors were measured and an oral glucose tolerance test wa
performed before and at the end of the study.

Compliance

Consumption of the experimental products was monitored using a computer programme
Products taken from the research shop were registered by means of a barcode reade
During the next visit, volunteers reported how much was left in stock at home and ho\
much was not consumed but thrown away. It appeared from the data of the foo
consumption diaries that in the reduced-fat group on average 37 g/day of fat intake wa
derived from the experimental products, for the control group this was 70 g/day. Th
mean daily fat intake from the experimental products remained stable during the stud
period. The remainder of their fat intake came from non-experimental products bought i
regular shops.

Procedures

Body weight: The subjects were weighed in underwear after an overnight fast four time
during the study (ED-60-T; Berkel, Ridderkerk, The Netherlands). From body weigl
and height body mass index (BMI; kg/m^2) was calculated.

Before and at the end of the study blood samples were drawn after an overnigl
fast for the analysis of indicators of the haemostatic system. For the analysis o
haemostatic factors blood was taken into ice-chilled tubes from the intermedian cubit
vein by a venoject system. After centrifugation for 10 min at 1700 g and 4°C the plasm
was collected, snap frozen and stored at --80°C until analysis.

PAI-1 antigen: To measure PAI-1 antigen blood was collected in CTAD buffer (0.11 N
citrate, 15 nM theophylline, 3.7 mM adenosine and 0.198 mM dipyridamole; Becto
Dickinson, Meylon, France). PAI-1 antigen was measured by means of an enzym
linked immunosorbent assay (ELISA) (Coalize® PAI-1/Innotest PAI-1, Chromogeni
AB, Möndal, Sweden).[26]

tPA activity: For measuring tPA activity blood was collected in Stabilyte tubes (Biopoo
Umeå, Sweden). tPA activity was measured with a bio-immunoassay for t-PA (Coatest
BIA t-PA, Chromogenix[27]). tPA antigen was measured with the Imulyse t-PA™ metho
(Biopool).

Fibrinogen: Fibrinogen was measured with a clotting rate method.[28]

Factor VII: Factor VII was measured with a chromogenic method (Chromogenix AB).

At the end of the run-in period and at the end of the experiment blood sample
were also drawn for the measurement of fasting glucose and insulin concentration:
Thereafter, an oral glucose tolerance test (OGTT) was performed: subjects drank 75

glucose in 250 ml water within 15 minutes. Then, at 4 moments after the glucose load (30, 60 90 and 120 min) another blood sample was drawn for the analysis of glucose and insulin concentrations. Fasting (t = 0) glucose and insulin concentrations, as well as the area under the curves (AUC), calculated by the trapezoidal rule and using t = 0 as the baseline value, were used as parameters in the analysis.

Plasma glucose concentrations were analysed with a commercially available kit (Boehringer Mannheim Diagnostica; Hitachi 911, Japan).

Plasma insulin concentrations were analysed with a commercial radioassay (Pharmacia) according to the kit protocol.

Statistics

BMDP statistical software was used for all statistical analyses.

Food intake & body weight:

The changes in energy and fat intake (as compared to baseline values), as well as changes in body weight and body mass index, that occurred during the intervention period were analysed with analysis of variance (ANOVA). This type of analysis is appropriate in detecting differences between groups, time effects and interactions. Students t-test was used to detect differences between groups at a certain moment in the study.

Haemostatic parameters & OGTT:

Since these parameters showed a non-normal group distribution the nonparametric Mann-Whitney U test for paired or unpaired data, as appropriate, was used.

Baseline correlations:

Pearsons correlations analysis was used to detect significant relationships between the parameters analysed.

Some gender differences were apparent at baseline: energy intake was higher in man than in women ($P < 0.001$); PAI-1 antigen levels were higher in man than in women ($P = 0.045$) and tPA activity and fibrinogen concentration were higher in women than in men ($P = 0.018$ and $P < 0.001$ respectively). However, no difference in intervention effects between men and women were observed. Therefore, data of the group as a whole are presented.

All values in the tables are expressed as mean ± SD. Probabilities of difference less than 0.05 were regarded as statistically significant.

RESULTS

The results on body weight and BMI for the 76 subjects participating at our Institute a
summarized in Table 9.1. Although body weight and BMI seemed to increase slightly
the control group repeated measures ANOVA did not reveal any significant time or di
effects in body weight or BMI.

Data on baseline energy and fat intake as well as the change during t
intervention period, as assessed by means of 3-day dietary records, are summarized
Table 9.2. Repeated measures ANOVA revealed a significantly stronger increase
energy intake in the control group as compared to the reduced-fat group. Ener;
percentage derived from dietary fat was significantly reduced in the reduced-fat group
compared to the control group. Repeated measures ANOVA also showed significa
effects on fatty acid intake: percentage energy derived from saturated fatty acid (SF/
mono-unsaturated fatty acids (MUFA) as well as polyunsaturated fatty acids (PUF
intake was significantly reduced in the reduced-fat group as compared to the conti
group. However, the change in PUFA intake in the reduced-fat group was no long
different from that in the control group at the end (after 6 months) of the stuc
Although a significant interaction was found in the ratio PUFA/SFA intake (PS-ratio),
difference in average changes between the groups was observed.

There appeared to be a large variation in the haemostatic parameters. No significa
effects on these parameters, PAI-1 antigen, tPA activity, Fibrinogen and Factor V
were observed (Table 9.3). Results from the oral glucose tolerance test are presented
Table 9.4. No differences in fasting glucose and insulin levels as well as in the ar
under the curves of glucose and insulin were observed (see also Figure 9.1).

At baseline, PAI-1 antigen was inversely related with tPA activity ($r = -0.5$
$P < 0.001$), and positively with fasting glucose concentration ($r = 0.384$; $P < 0.00$
(Figure 9.2a). Closer examination of this relationship revealed that two outliers appear
in this plot. However, correlation analysis without these outliers showed an ev
stronger relationship between PAI-1 antigen and fasting glucose concentrati
($r = 0.483$; $P < 0.001$). PAI-1 antigen also correlated with the AUC of insu
($r = 0.323$; $P = 0.005$). tPA activity inversely correlated with baseline gluc
concentrations ($r = -0.267$; $P = 0.019$) (Figure 9.2b). Fibrinogen concentration correlat
with the AUC of glucose ($r = 0.236$; $P = 0.040$) (Figure 9.2c). Factor VII concentrati
was significantly related with fasting insulin levels ($r = 0.321$; $P = 0.005$) (Figure 9.2
with the AUC of insulin ($r = 0.245$; $P = 0.037$), and nearly significantly related with t
AUC of glucose ($r = 0.218$; $P = 0.058$). The AUC of glucose correlated with that
insulin ($r = 0.477$; $P < 0.001$).

Figure 9.1. Glucose (top) and insulin (bottom) concentrations during the oral glucose tolerance test (OGTT) at baseline and at the end of 6 months consumption of reduced fat products.

Table 9.3. Fibrinolytic factors at baseline and the change (Δ) after six months of consumption of eith reduced fat products or their full fat equivalents (control). Data are shown as x̄ ± sd.

	Control group		Reduced fat group		P
					ΔCtrl vs.
	baseline	Δ	baseline	Δ	ΔRed.fat
PAI-1 antigen (ng/ml)	58.1 ± 42.2	8.1 ± 39.7	62.0 ± 59.9	-1.9 ± 37.8	NS
tPA activity (mIU/ml)	289 ± 145	1 ± 169	272 ± 140	57 ± 192	NS
Fibrinogen (g/l)	2.90 ± 0.50	0.16 ± 0.52	2.83 ± 0.63	0.20 ± 0.51	NS
Factor VII (%)	99 ± 29	2 ± 14	115 ± 21	-3 ± 16	NS

Table 9.4. Results from the oral glucose tolerance test at baseline and the change (Δ) after six months consumption of either reduced fat products or their full fat equivalents (control). Data a shown as x̄ ± sd.

	Control group		Reduced-fat group		P
					ΔCtrl vs.
	baseline	Δ	baseline	Δ	ΔRed.fat
Glucose (mM) t = 0	5.02 ± 0.44	0.35 ± 0.31	5.10 ± 0.53	0.27 ± 0.33	NS
Insulin (mM) t = 0	6.34 ± 1.83	0.62 ± 1.95	7.19 ± 1.69	0.49 ± 2.27	NS
AUC Glucose	133 ± 140	-15 ± 118	152 ± 131	-14 ± 123	NS
AUC Insulin	2689 ± 1444	300 ± 1143	3490 ± 2505	167 ± 1700	NS

Furthermore, BMI was significantly related with PAI-1 antigen ($r = 0.496$; $P < 0.001$ tPA activity ($r = -0.459$; $P < 0.001$), fasting glucose concentration ($r = 0.41$; $P < 0.001$), the AUC of glucose ($r = 0.326$; $P = 0.004$) and the AUC of insul ($r = 0.281$; $P = 0.016$). Partial correlation analysis after removing the linear effe between BMI and AUC of insulin revealed that the correlation between BMI and PAI antigen, tPA activity as well as fasting glucose level were still significant ($r = 0.45$ $P < 0.001$; $r = -0.408$, $P < 0.001$; $r = 0.390$, $P < 0.001$ respectively).

The age of the subjects correlated with baseline PAI-1 antigen concentratic ($r = 0.353$; $P = 0.002$), with fasting glucose concentration ($r = 0.360$; $P = 0.001$) an with the AUC of insulin ($r = 0.247$; $P = 0.035$). After removing linear effects betwee age and AUC of insulin, the relationships between age and PAI-1 antigen as well fasting glucose concentration were still significant ($r = 0.280$, $P = 0.014$; $r = 0.32$ $P = 0.005$ respectively).

DISCUSSION

The aim of the present study was to investigate whether realistic consumption of reduced-fat products beneficially affects indicators of the haemostatic system. Moreover, the effects on glucose tolerance and its relationship with indicators of the haemostatic system has been studied. Previously, we reported that restriction of the energy intake, while keeping relative contributions of the macronutrients constant, beneficially affects fibrinolytic parameters in non-obese men, especially in those with a high PAI activity. These effects were related to the decrease in BMI.[29] However, it is hard to differentiate whether these effects on fibrinolytic factors are the consequence of the reduction in the total amount of dietary fat or to the weight loss. It has been reported that a moderate reduction in dietary fat did not influence blood coagulation and fibrinolysis.[30] However, diet might be involved in the haemostatic system since results from intervention studies, reported by Marckmann, showed that a 2-week low-fat/high-fibre diet lowered Factor VII caogulant activity and raised plasma fibrinolytic activity.[31] In addition, consumption of a low-fat/high-fibre diet (26% of energy derived from fat, 58% of energy derived from carbohydrates; P/S-ratio = 0.77) for 8 months elevates tPA activity as well as the systemic fibrinolytic activity of the euglobulin fraction of plasma. Both effects were already apparent after 60 days.[32] These studies suggest that macronutrient composition plays a role in fibrinolytic activity. However, Marckmann's intervention studies were performed under dietary controlled conditions, using a diet which seems not to be realistic under 'free living' conditions.

The present study showed that consumption of reduced fat products under realistic conditions resulted in a significantly lower energy intake as well as in a lower contribution of fat to energy intake when compared to consumption of their full-fat equivalents. However, in the present study no effect of diet on selected fibrinolytic parameters could be detected in healthy non-obese subjects. This result does not exclude that indicators of haemostatic system are not affected by consumption of reduced fat products in subjects with higher risk for CHD either. The observed beneficial effects in Marckmann's long-term study cannot be explained by weight reduction, since body weight at the end of the study did not differ from initial values, after a drop of 1.4 kg on average midway in the study.[33] Therefore, it seems that, if macronutrient composition plays a role in the haemostatic system, a more complex and relatively large dietary change, as implemented by Marckmann, has to be realised in order to affect haemostasis.
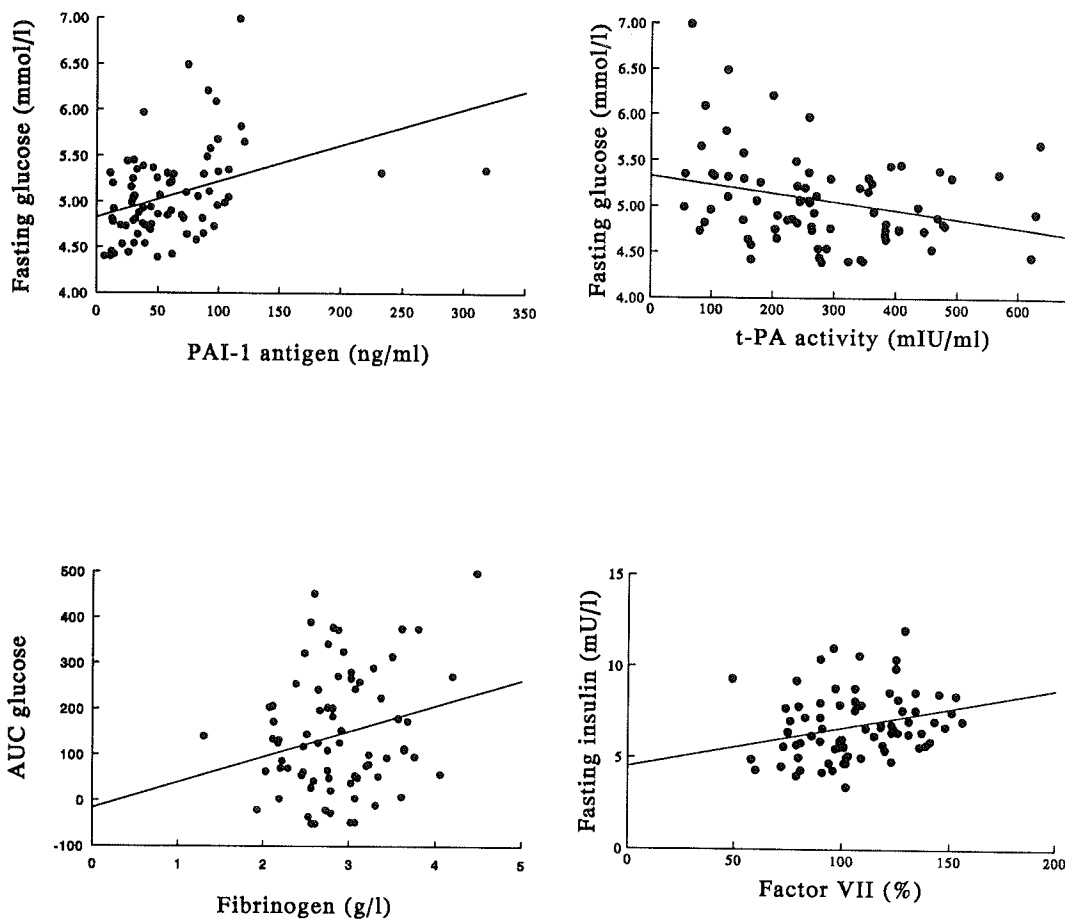

Figure 9.2. Baseline relationships between haemostatic factors and parameters of the oral gluco:
tolerance test.
a) (upper left): PAI-1 antigen versus fasting glucose concentration (r = 0.384; P < 0.001)
b) (upper right): t-PA activity versus fasting glucose concentration (r = –0.267; P = 0.019)
c) (lower left): Fibrinogen concentration versus AUC of glucose (r = 0.236; P = 0.040).
d) (lower right): Factor VII versus fasting insulin concentration (r = 0.321; P = 0.005).

Apart from total fat consumption the composition of dietary fatty acids might also affect the haemostatic system. However, reports on this relationship are conflicting as both an increase in PAI activity has been reported after 4 months of fish consumption,[34] as well as a decrease in PAI activity after fish oil supplementation.[35] Also, no effect on haemostatic factors after n-3 PUFA supplementation has been reported.[36] Recently, it has been reported that the effect of n-3 fatty acids on platelet and vascular function is modulated by the content of saturated fatty acids in the diet.[37] In the present study percentage energy derived from total PUFA's was ca. 1.5 en% lower in the reduced-fat group when compared to the control group, which was statistically significant. No effect of this relatively small change in PUFA intake on haemostatic parameters was observed. In addition, no significant relationship could be demonstrated between fatty acid intake (PUFA, SFA, PUFA/SFA ratio) and the haemostatic parameters measured. Unfortunately, our data do not allow further distinguishment between the various PUFA's.

In agreement with previous reports we found a significant correlation between BMI and several parameters of haemostasis and OGTT. Others have reported a significant positive relationship between PAI-1 antigen concentration and fasting insulin levels in subjects with a wide range of BMI,[38] and in a group including diabetic and obese subjects.[39] We did not observe such a relationship in the present study. However, a significant relationship between the AUC of insulin and PAI-1 antigen concentration was observed, confirming a relationship between fibrinolysis and insulin sensitivity in healthy, non-obese subjects. The relationship between BMI and PAI-1 antigen concentration and tPA activity was still significant after correction for the AUC of insulin, suggesting an independent relationship between BMI and fibrinolysis.

Since both the age of the subjects as well as the BMI was positively related to PAI-1 antigen concentration and AUC of insulin, it could be suggested that older subjects with a higher BMI could benefit more from consumption of reduced fat products than the younger and leaner subjects. However, after dividing the reduced-fat group in two age categories, no differences in changes in haemostatic parameters after 6 months was observed. Nor was there any statistically significant difference between different BMI subgroups, or between combinations of age and BMI subgroups.

In conclusion, realistic consumption of reduced-fat products leads to a significantly lower energy intake and as well as to lower percentage of energy derived from dietary fat as compared to consumption of full-fat equivalents. However, this did not result in a change in the CHD risk markers PAI-1 antigen, tPA activity, fibrinogen concentration, Factor VII concentration and insulin sensitivity. However, since this study is performed in healthy non-obese subjects it does not exclude that consumption of reduced fat products does not affect haemostatic parameters in subjects with a higher risk for CHD.

ABSTRACT

It is widely held that energy restriction (ER) retards the ageing process. The beneficial effects of ER has repeatedly been demonstrated in laboratory rodents, but ER might also be effective in humans since ageing seems to be a universal phenomenon in all living organisms. Reduced oxidative stress, induced by the maintenance or improvement of the antioxidant/prooxidant balance, has been mentioned as a potential mechanism through which ER might affect the ageing process in rodents. Oxidative stress can also be affected by the total dietary fat intake as well as fatty acid composition. In this paper we present the effects of 6-month consumption of reduced-fat products on body weight, energy and fat intake, concentration of the plasma lipidperoxidation product malondialdehyde (MDA), erythrocyte free radical scavenging enzymes activities (glutathione peroxidase activity, GSH-Px; superoxide dismutase, SOD; and catalase) as well as plasma fat-soluble antioxidative vitamin concentrations (β-carotene, lycopene and α-tocopherol). The reduced-fat products were provided through a realistic shop in order to mimic a 'free living' situation. Healthy, normal weight (BMI: range 20-30 kg/m^2) subjects (n = 76), aged between 20-55 yr, participated in this study. During the intervention period, consumption of reduced fat products resulted in significantly lower energy intake, in a lower percentage of energy derived from saturated fatty acids, monounsaturated fatty acids and polyunsaturated fatty acids as well as in lower vitamin E intake, when compared to the control group. Body weight, the ratio polyunsaturated fatty acids/saturated fatty acids, plasma MDA and vitamin concentrations (β-carotene, lycopene and α-tocopherol), and erythrocyte free radical scavenging enzyme activities (SOD, GSH-Px and catalase) were not affected by the

intervention. It is concluded that neither the difference in energy intake, nor the chang in dietary fat composition seems to affect the integrity of the antioxidant scavengin capacity, assessed by measuring plasma MDA and antioxidative vitamins (lycopen β-carotene and α-tocopherol) and erythrocyte free radical scavenging enzymes (SOI GSH-Px and catalase).

INTRODUCTION

It is widely held that energy restriction (ER) retards the ageing process.[1] Th 'life-extension effect' has repeatedly been demonstrated in various rat and mous strains.[1] The beneficial effects of ER has been extensively studied and evaluated i laboratory rodents, but ER might in principle also be effective in humans since agein seems to be a universal phenomenon in all living organisms. A potential mechanisr through which ER might affect the ageing process in rodents is the maintenance c improvement of the antioxidant/prooxidant balance, leading to reduced oxidative stress.

It is difficult, if not impossible, to mimic the life-long animal studies in huma volunteers, and to extrapolate the results of ER observed in animals to man. Howeve one of the strategies to evaluate whether similar effects of ER could be achieved i humans is to test whether a certain physiological system, related to the ageing process i an animal model, is also affected by ER in humans. For example, one could test wheth the effects of ER on maintenance or improving the antioxidant/prooxidant balance, i. reduction of oxidative damage, as observed in ageing rodents, could also h demonstrated in humans.

Apart from conceptual and/or mechanistic considerations implementation of a ER-diet, tenable for longer periods and under 'free living conditions', seems to be prerequisite before studying potential health- and age-retardation effects in humans.

Since dietary fat provides the most concentrated source of energy, decreasing th amount of dietary fat intake may be an option to reduce the energy intake. Dietary f intake is higher than recommended in most western countries and is associated with th prevalence of cardiovascular diseases, obesity and cancer. The growing public concer about the adverse effects of a high fat intake has led to an increased availability c 'reduced-fat' products. Consumption of reduced-fat products might be a convenient wa to reduce the energy intake.

Besides the potential of reduced energy intake changes in dietary fat intak qualitative and quantitative, might also affect oxidative stress, i.e. th antioxidant/prooxidant ratio. Polyunsaturated fatty acids (PUFA's) contain two or mor double bonds within their structure which makes them more susceptible to oxidativ

damage by free radical attack. A secondary effect of reduced fat intake might be a reduced intake and/or absorption of fat-soluble antioxidative vitamins. In this regard, the total antioxidative capacity in the cell, determined by antioxidative vitamins and free radical scavenging enzymes, should be considered.

The present study was performed in order to investigate the potential of reduced-fat products to reduce the energy intake. The reduced-fat products were provided through a realistic shop in order to mimic a 'free living' situation. Also, it was investigated whether consumption of reduced-fat products alters dietary fat intake or fatty acid composition. Since both energy restriction as well as dietary fat intake might affect the antioxidative capacity, parameters that could affect the antioxidant/prooxidant balance were measured.

In this paper we present the effects of 6-month consumption of reduced-fat products on body weight, energy and fat intake, concentration of plasma lipid peroxidation product malondialdehyde (MDA), erythrocyte free radical scavenging enzymes activities (glutathione peroxidase activity, GSH-Px; superoxide dismutase, SOD; and catalase) as well as plasma fat-soluble antioxidative vitamin concentrations (β-carotene, lycopene and α-tocopherol). Furthermore, correlations between (changes in) fat intake and (changes in) parameters of the antioxidant/prooxidant balance, as well as between these various parameters were calculated.

SUBJECTS AND METHODS

Subjects

Eighty apparently healthy subjects (40 men, 40 women) started as a participant in the study. They were selected from responders to advertisements in regional newspapers. Subjects were aged between 20 and 55 yr. Those aged between 20 and 35 yr had a body mass index (BMI) between 20 and 28 kg/m^2, and those aged between 35 and 55 yr had a BMI between 24 and 30 kg/m^2. All subjects were medically screened by a physician. Routine clinical chemistry, blood pressure and lipid profile had to be within normal ranges. Exclusion criteria were: following a medically prescribed diet or slimming diet; being pregnant or wishing to become pregnant during the experiment; weight loss or gain > 2 kg/month 1 month before prestudy examination; and sporting activities of more than 7 hrs/week. Subjects were randomly assigned to either the reduced-fat group or the control group which received the full-fat equivalents. The groups were stratified according to sex, age, BMI, eating behaviour characteristics and type of household. Four females from the control group withdrew from the study because one disliked the taste of the products, one got pregnant, and two because of changed personal circumstances,

so that 36 subjects in the control group and 40 in the reduced-fat group finished th
study.

The study protocol was approved by the Institute's Medical Ethical Committee an
the participants signed an informed consent form.

Study design

The study was part of a multicentre study, the MSFAT-study, on the long-term heal
effects of realistic consumption of reduced-fat products in healthy non-obese volunteer
The design was a randomized 6 month parallel comparison trial which has bee
described extensively elsewhere (Chapter 8).[5] In short, four Dutch research centre
participated in the study. One centre was responsible for coordination of the study, th
other three centres selected each about 80 volunteers. A realistic shop was installed
these three centres. Two months before the start of the study, a one month adaptatic
period was executed to optimize the experimental procedures and to get the voluntee
used to these procedures. Volunteers were free to take as many of the reduced f
products or their full fat equivalents (e.g. spreads, dressings, frozen meals, cheeses, me
products, non-dairy creams, biscuits, snacks etc.) as they wanted. They were also free
buy non-experimental products such as bread and vegetables in regular shops. In th
three centres food intake was assessed before the adaptation period, after 2 weeks,
months and at the end of the study by 3-day food consumption diaries, estimatin
quantities in household measures. Fasting blood levels were taken before, after tw
months, four months and at the end of the study. On the same days body weight wa
assessed. Before and at the end of the study body composition was measured. Next
these general measurements research centre-specific measurements were performed.
the subjects participating at our Institute biomarkers of oxidative stress, malondialdehyc
(MDA), free radical scavenging enzymes (GSH-Px, SOD and catalase) and plasn
antioxidative vitamin concentrations (β-carotene, lycopene, α-tocopherol) were measure

Compliance

Consumption of the experimental products was monitored using a computer programm
Products taken from the research shop were registered by means of a barcode reade
During the next visit, volunteers reported how much was left in stock at home and ho
much was not consumed but thrown away. It appeared from the data of the foc
consumption diaries that in the reduced-fat group on average 37 g/day of fat intake wa
derived from the experimental products, for the control group this was 70 g/day. Th
mean daily fat intake from the experimental products remained stable during the stuc
period. The remainder of their fat intake came from non-experimental products bought
regular shops.

Procedures

Body weight: The subjects were weighed in underwear after an overnight fast four times during the study (ED-60-T; Berkel, Ridderkerk, The Netherlands). For the measurement of body composition, total body water (assuming to be 73% of subjects' fat-free mass) was determined by deuterium dilution. Subjects drank a weighed dose of labelled water after emptying the bladder at 22:00. This was the baseline urine sample. Another sample was collected the next morning from the second voiding. Deuterium was measured in the urine samples with an isotope ratio mass spectrometer (VG-Isogas Aqua Sira).[6]

Blood was drawn from an antecubital vein after an overnight fast for the following measurements. All analyses were performed in the same period at the end of the study.

Plasma malondialdehyde (MDA): For the analysis of MDA blood samples were put in liquid nitrogen immediately after collection and stored at –80°C until analysis. MDA content was measured after pre-column derivatisation with thiobarbituric acid (TBA) using HPLC and a fluorescence detector as described by Young and Trimble.[7]

For the analysis of *catalase, GSH-Px and SOD in erythrocytes* heparinized blood was collected. Erythrocytes were washed three times and stored under helium at –80°C until analyzed. *Catalase activity* was measured by monitoring substrate (H_2O_2) disappearance spectrophotometrically (LKB, Cambridge, UK) at 240 nm according to the method of Aebi.[8] The activity of *GSH-Px* was measured according to a 'FLAIR-standardized method.[9] This FLAIR assay is based on the method of Paglia and Valentine's,[10] including an enzyme stabilization step and using t-butyl hydroperoxide rather than hydrogen peroxide. *SOD-activity* was measured spectrophotometrically (LKB, Cambridge, UK) using the RANSOD kit (Randox laboratories, Ireland) according to the kit's protocol.

Plasma samples for analysis of concentrations of β-*carotene, lycopene and* α-*tocopherol* were stored under argon at –70°C until analysis. After extraction, β-carotene and lycopene were separated by HPLC on Nucleosil 5-N(CH_3)$_2$ column (Machery & Nagel, Duren, Germany) with n-heptane as the mobile phase. The chromatographic system for α-tocopherol consisted of a Nucleosil 5CN column and a mobile phase of n-heptane/dichloromethane/isopropanol (90:10:0.2, v/v) for 5 min followed by n-heptane/dichloromethane/isopropanol (90:10:2, v/v) for 20 min at a flow rate of 1 ml/min.

Statistics

Intervention effects

The changes (as compared to baseline values) that occurred during the intervention period were analysed with analysis of variance (ANOVA) with repeated measures using BMDP statistical software. This type of analysis is appropriate in detecting differences

between groups, time effects and interactions. Students t-test was used to dete
differences between groups at a certain moment in the study.

Correlations (n = 76)

To assess relationship between food intake and the parameters analysed at baselir
Pearson's linear correlation coefficient was calculated. Since most variables appeared
be quite variable during the intervention period, the mean of the three samples take
during the intervention period was also used as a variable in Pearson's linear correlatio
analysis. Relationships between changes (Δ at six months as compared to baseline)
variables were also calculated with Pearson's linear correlation coefficient.

As no differences were observed in ANOVA-analysis using gender as a groupir
factor, data from male and female subjects are pooled. P-values were considere
statistically significant at P < 0.05. Results are expressed as means ± standard deviatic
(sd).

RESULTS

Intervention effects

The results on body weight, BMI and body composition for the 76 subjects participatir
at our institute are summarized in Table 10.1. Although body weight and BMI seemed
increase slightly in the control group repeated measures ANOVA did not reveal ar
significant time or diet effects in body weight or BMI. In addition, no significant effec
on body composition were found.

Food intake as assessed by means of 3-day dietary records is summarized
Table 10.2. Repeated measures ANOVA revealed a significantly stronger increase
energy intake in the control group as compared to the reduced-fat group. Energ
percentage derived from dietary fat was significantly reduced in the reduced-fat group
compared to the control group. Repeated measures ANOVA also showed significa
effects on fatty acid intake: percentage energy derived from saturated fatty acid (SF/
mono-unsaturated fatty acids (MUFA) as well as polyunsaturated fatty acids (PUF/
intake was significantly reduced in the reduced-fat group as compared to the contr
group. However, the change in PUFA intake in the reduced-fat group was no long
different from that in the control group at the end (after 6 months) of the stud
Although a significant interaction was found in the ratio PUFA/SFA intake,
difference in average changes between the groups was observed. Vitamin E intake, bc
expressed in absolute terms as well as per gram PUFA, decreased significantly in t
reduced-fat group.

Table 10.3 presents the results on lipid peroxidation measured as plasma MDA concentration, the free radical scavenging enzymes GSH-Px, SOD and catalase and th antioxidative enzymes β-carotene, lycopene and α-tocopherol. None of these parameter changed differently between groups. Both groups showed a decrease in GSH-Px activit and an increase in SOD activity during the intervention period. Catalase activity showe a more variable pattern, i.e. a decrease at two months and an increase at four and si months in both groups.

Correlations

At baseline, a relationship between erythrocyte GSH-Px activity and SFA intak (r = 0.273; P = 0.017), as well as an inverse relationship between GSH-Px and catalas activity (r = –0.388; P < 0.001) was found. Plasma MDA concentration correlated wit plasma α-tocopherol concentration (r = 0.413; P < 0.001). Plasma lycopene an β-carotene concentrations were related (r = 0.295; P = 0.010). Age was inversely relate to energy intake (r = –0.258; P = 0.024), and positively related with plasma β-caroten concentrations (r = 0.295; P = 0.010) as well as with plasma α-tocopherol concentration (r = 0.422; P < 0.001). However when plasma α-tocopherol was expressed as per mmc cholesterol, this association was no longer significant. Age did not correlate with th activity of the free radical scavenging enzymes GSH-Px, SOD and catalase.

Considering the mean values calculated for the intervention period, GSH-P activity again correlated negatively with catalase activity (r = –0.462; P < 0.001 Contrary to the baseline correlation analysis, a negative correlation between GSH-P activity and SOD activity was observed (r = –0.446; P < 0.001). SOD activity, in turr correlated with MUFA intake (r = 0.406; P < 0.001) and negatively with the age of th subjects (r = –0.251; P = 0.035). Age did not correlate significantly with the activity c the other two free radical scavenging enzymes, GSH-Px and catalase. Furthermore, ag was inversely related with energy intake (r = –0.330; P = 0.004), as well as with plasm lycopene concentration (r = –0.342; P = 0.003). Plasma α-tocopherol concentratio correlated with the age of the subjects (r = 0.432; P < 0.001). Again, when α-tocopherc was expressed as per mmol cholesterol this association was no longer significant. Plasm MDA concentration correlated with plasma α-tocopherol (r = 0.268; P = 0.022). N correlation between vitamin E intake and plasma α-tocopherol concentration was found.

There was a significant relationship between the change in MUFA intake and th change in catalase activity (r = –0.317; P = 0.007). Changes in plasma β-caroten concentrations were related with changes in lycopene (r = 0.406; P < 0.001) as well a with changes in α-tocopherol concentrations (r = 0.256; P = 0.030). No other significar correlations between changes have been observed

DISCUSSION

Intervention effects

Since it has been suggested that energy restriction might retard the ageing process in humans, we reported before about the feasibility of an imposed moderately energy restricted diet in non-obese men.[11] In the present study we investigated the potential of reduced-fat products to reduce the energy intake. The influence of reduced-fat products on energy-balance has been studied in many short and long-term studies which have been summarized by Bellisle and Perez.[12] The authors concluded that the longest experiments on reduced-fat feeding suggest that some compensatory increase in intake progressively develops, but does not completely reverse the modest weight loss that occurred during the first few weeks on the reduced-fat diet. However, the studies summarized were performed under strictly controlled conditions. The present study was designed to mimic a 'free living' situation by installing a realistic shop where subjects can go on errands weekly, and are free to buy additional food products elsewhere. The results of this study showed that consumption of reduced-fat products under 'free living conditions' leads to a significantly lower energy intake as compared to consumption of their full-fat equivalents. These results are in agreement with previous suggestions that macronutrient composition plays a role in energy intake.[13]

Reduced energy intake might retard the ageing process through maintenance or improvement of the prooxidant/antioxidant balance.[14,15] However, the difference in energy intake between the reduced-fat group and the control group achieved in this study, however, did not result in an effect on plasma MDA concentration, plasma antioxidative vitamins and erythrocyte free radical scavenging enzymes during the intervention period.

Activities of these enzymes changed similarly in both groups. The fluctuations observed are not easily to explain. Time of storage, or storage conditions, seem to be an unlikely cause as in this case one would expect that blood samples drawn at the end of the study show higher activity than those drawn at the start of the study. However, none of the enzyme activities measured in this study showed a linear trend to increase during the study. In addition, since all samples of one subject were analysed in the same run, variation in analytical procedures does also not explain the changes observed either.

Besides restriction of the energy intake, the quantity and composition of dietary fat intake might also affect fat-soluble antioxidative vitamin intake and/or antioxidative capacity and lipid peroxidation status. Fats in foods serve as a carrier for fat-soluble vitamins. Reduced-fat foods might therefore adversely affect the availability of fat-soluble vitamins and subsequently antioxidative capacity, since both vitamin E and

carotenoids act as an antioxidant. Most of the reports on reduced fat products an plasma vitamin concentrations refer to the effects of a non-caloric sucrose polyeste (SPE), not allowed to be used as a fat-substitute in The Netherlands yet. Consumption c SPE decreases plasma vitamin A and E concentrations after 10 days in healthy subjec receiving normal diets in which SPE was introduced by addition or substitution[16] as we as after 16 weeks in obese subjects receiving hypocaloric diets, containing 25% c calories of fat plus SPE.[17] Results from our study show that 6 months realisti consumption of reduced fat products did not affect plasma lycopene and β-caroten concentrations. It has been reported that dietary intake of lycopene[18] and β-carotene reflect their serum concentrations. Although we had no data on lycopene and β-caroten intake, it might therefore be speculated that intake of these carotenoids did not chang during the study. Remarkably, plasma concentration of α-tocopherol did not chang either, despite a decrease in vitamin E intake. Vitamin E intake, as well as the vitamin per gram PUFA intake, decreased significantly in the reduced-fat group. The intake c 0.37 ± 0.16 mg vitamin E per g PUFA in this group at the end of the study becam even lower than the recommended intake of 0.4 mg/g, needed to maintain tissu concentrations.[20] This finding might suggest that 'usage' of plasma α-tocopherol i decreased in the reduced-fat group. However, this aspect might need further attention.

Correlations (n = 76)

Reports on the relationship between dietary fatty acid intake and free-radical scavengin enzymes are scarce, especially those performed in humans. It has been observed that diet rich in oleic acid (18:1n-9; MUFA) lead to lower hepatic catalase activity in mice. In our study fatty acid intake did not correlate with catalase activity, neither at baselin nor during the intervention period. However, MUFA intake increased in the contr group and decreased in the reduced-fat group. Pooling the two groups, a significar inverse relationship between the change in MUFA intake and the change in erythrocyt catalase activity after 26 weeks was observed ($r = -0.317$, $P = 0.007$), which is i agreement with the observation in mice. In mice, no effects of dietary fatty acic composition on hepatic GSH-Px activity and MDA levels was found,[21] whereas or supplementation of 20 ml fish oil (PUFA) for 10 weeks in humans led to increase GSH-Px activity.[22] In our study no correlation between GSH-Px activity and percentag energy derived from PUFA was observed, whereas no relationship between plasm MDA concentration and dietary fatty acid composition was found. The chang accomplished in our study are most probably not that extreme to alter the enzym activities measured.

In this study a negative correlation between catalase and GSH-Px has been found. This inverse relationship has been observed in various species.[23] Since both enzymes detoxify H_2O_2 this might suggest that a compensatory relationship may exist. A correlation between SOD and catalase might be expected since catalase is thought to account for a notable part of the elimination of H_2O_2, which is partly generated by SOD. Others also failed to show a correlation between catalase and SOD activity[23,24] but the reason remains unclear.

A positive correlation between MDA and plasma α-tocopherol has been found in the present study. A possible explanation is that a high PUFA intake, which is attended with high vitamin E intake, leads to a high plasma α-tocopherol concentration as well as to a high MDA concentration. However, correlation analysis did not support this hypothesis.

Many reports on animal studies suggest a decline in free radical scavenging capacity with advancing age. This is in line with the 'Free radical theory of ageing', formulated by Harman,[25] which postulates that ageing is caused by free radical reactions. Sohal and Allan[26] further elaborated on this theory and postulated that ageing is due to a dysbalance between prooxidants and antioxidants within cells. In line with Sohal and Allan's hypothesis, a negative correlation between age and SOD activity as well as between age and lycopene was found in this study, considering mean values of the intervention period.

Cutler[27] presented evidence supporting Harman's 'rate of living theory' by showing that the species-specific basal metabolic rate is inversely related to life span. To assess whether such a relationship is also present in the subjects participating in this study, basal metabolic rate (BMR) was calculated from their fat mass and fat-free mass according to the formula: BMR (MJ/day) = 0.102*FFM(kg) + 0.024*FM(kg) + 0.85.[28] Correlation analysis between calculated BMR and the parameters measured revealed that the relationship between BMR and GSH-Px activity at baseline nearly reached significance ($r = -0.219$; $P = 0.057$), but the mean value of the intervention period correlated significantly with calculated BMR at the end of the study ($r = -0.294$; $P = 0.011$). BMR correlated also with plasma β-carotene concentration both at baseline ($r = -0.334$; $P = 0.003$), as well as during the intervention period ($r = -0.284$; $P = 0.014$). Interpretation of these associations is difficult, but one could hypothesize that, according to the 'rate of living theory', those with a higher BMR might be more susceptible to oxidative damage, due to lower GSH-Px activity and lower β-carotene concentrations.

From this study it can be concluded that in the given context, the consumption reduced-fat products lead to lower energy intake as compared to consumption of the full-fat equivalents. Furthermore, consumption of reduced-fat products decreased vitam E intake and altered dietary fatty acid composition. However, neither the difference energy intake, nor the change in dietary fat composition seemed to affect the integrity the antioxidant scavenging capacity, assessed by measuring plasma MDA an antioxidative vitamins (lycopene, β-carotene and α-tocopherol) and erythrocyte fre radical scavenging enzymes (SOD, GSH-Px and catalase).

General Discussion

There seems ample evidence to conclude that ER extends both mean and maximum lifespan of species, representing different types of animals such as a nematode (Caenorhabditis elegans), the fruit fly (Drosophila melanogaster) and rodents (Mus and Rattus).[1-3] Moreover, ER decreases susceptibility to several diseases in rodents.[1] However, the finding that ER beneficially affects the ageing process has been criticized by saying that the relationship between ER and ageing supports an opposite interpretation as well, namely that dietary excess, as often seems to be the case in caged animals, reduces life span.[4] This argument can be countered by a study of Weindruch et al.[5] who reported that up to the point where ER approaches an actual starvation level, still a relationship between the level of ER and life span extension could be demonstrated. However, one can still argue that improvement in rodent life-span is a result of being spared a pathological environment. With respect to the potential application of ER in humans the question is whether we have lost the type of response exhibited by rodents due to control of our evolutionary environment or that we have optimized our environment during evolution and have reached maximum life span already.

So, we do not know whether humans have the capacity to respond to ER with postponed ageing. Therefore, the intriguing, phylogenetically independent anti-ageing effect of ER raises several questions with regard to human ageing: 1) could some (or all) of these effects be realized in man on an appropriate ER regimen, or is the life prolonging effect of ER just a phenomenon unique to short-lived species?; 2) can ER extend human life span beyond its present limit of 110-115 years?; 3) does ER also extend health span (i.e. time until the onset of age related diseases) and if so, what is the underlying mechanism?; 4) at what age should an energy restricted diet be introduced?; etc. As, to our knowledge, no previous reports have been published into the relevance of findings from animal studies to man, the studies described in this thesis are a first attempt. Although it is hard, if not impossible, to assess whether humans have the capacity to respond to ER with postponed ageing, several approaches can be considered as an effort to answer these questions such as studying in-vitro cultures of mammalian cells or studying gene expression.[6] However, in our opinion a prerequisite before studying potential age-retardation effects in humans is to study the potential of implementation of

an ER-diet tenable for the longer term, as well as to investigate potential health risks (benefits of ER. Next, short term effects of ER in humans on physiological system related to the ageing process could be compared with short- and long term effects of E in animals. In this Chapter these items will be discussed after a brief remark about th social aspects of ER.

SOCIAL ASPECTS OF LIFE EXTENSION BY ENERGY RESTRICTION

Several people will object against attempts to postpone human ageing by energ restriction as they feel that extending life span is socially unacceptable and could lead high costs of health care for the elderly. The ethical aspects and the social desirability (postponing ageing are beyond the scope of this thesis. However, ER will presumably n be adopted by an entire population, even if it was proven to be successful. If a subgrou of subjects chooses to follow an energy restricted diet, adequate in essential nutrient this will most probably not lead to drastic social changes. Besides, as society w probably benefit more from extension of health span in stead of extension of life span, is also interesting to study whether ER could extend health span.

Since energy restriction is most probably the most suitable model to study th ageing process, it might at least provide insight in the human ageing process.

POTENTIAL OF IMPLEMENTATION OF ENERGY RESTRICTION

What level of ER will be appropriate in man
The level of ER that will be appropriate in man for the longer term is uncertain. In th semistarvation study Keys and colleagues[7] showed that 50% ER is not acceptable for tl longer term as it appeared to introduce several negative health effects (symptoms apathy and listlessness, ultimately leading to severe energy malnutrition). Therefore, the first study the level of ER was aimed at 20%. However, due to underreporting habitual energy intake the actual level of ER appeared to be approximately 30%. Fro the results on energy expenditure and body composition, described in Chapter 5, it c be concluded that the imposed level of 30% ER was actually too high to be regarded acceptable for the longer-term. From this finding, in conjunction with the slightly, b significantly decreased physical performance (Chapter 4), it can be concluded that if E is to be implemented for the longer term it should be at least at a milder level than 30 Even when a level of 20% ER had been imposed in these subjects, then, according tc computer simulation model,[8] subjects' body fat would decrease to ca. 5.6% and th

would still be in negative energy balance after a period of one year. A level of 4-6% (or ca. 2.5 kg) body fat has been suggested to be the lower limit in healthy men, and represents the point at which individuals enter a phase of increased muscle catabolism.[9] Thus, 4-6% body fat should be considered as an absolute minimum. Therefore, even this 20% ER level would be too high for the longer term. According to Weindruch and Walford, a daily intake of 6.3-8.4 MJ/day (1,500-2,000 kcal) will induce a gradual weight loss in men, and if it includes RDA's of all essential nutrients, can hardly be regarded as a dangerous program. As energy intake was 9.2 MJ/day on average during the intervention period in the subjects in the ER group, Weindruch and Walford's recommendation should be regarded as too low.

As a consequence of the underreporting, subjects in the control group were restricted in their intake too, but at a very mild level. In contrast to the ER group, subjects in the control group seemed to stabilize at the end of the 10-week study, after which they had lost 2.1 kg on average. This mild level of ER, most probably 10%, seemed to be acceptable for the longer term, but did not result in beneficial effects on blood pressure, lipid profile or fibrinolytic factors after 10 weeks.

From studies on genetically obese mice it seems unlikely that, within certain limits, the amount of body fat plays a crucial role in the ageing process. When energy intake is restricted in these mice their life span is extended past that of normal mice fed ad libitum, even though their body weight and percentage of body fat remain significantly higher than those of non-obese mice.[10] Therefore, another approach of imposing ER is related to the concept of an equilibrium 'set point', which argues that the body defends a particular weight by shifting the energy efficiency of the metabolic machine.[11] According this set-point theory each individual has a particular set-point determined by genetic endowment plus his/her early feeding history. The response to decreased energy intake is to increase efficiency in order to maintain body weight. Weindruch and Walford assume that any degree of sustained weight loss below the genetic set-point of the individual might yield survival benefits in terms of maximum as well as average life span.[1] They elaborate on this by suggesting that for individuals whose body weight has been stable since ages 20-30 that body weight is precisely their set-point. For those who have gradually gained body weight, the appropriate set point is uncertain, but would be their weight at 20-30 years. Although the existence of such a set-point has been questioned[12] this approach of stabilizing at a body weight below one's body weight at 20-30 years will most probably be more feasible than imposing a longer-term fixed level of ER. As the subjects in the ER group in our first study lost approximately 10% body weight, without any obvious injurious effects, it would have been interesting to study the long-term effects after they were stabilized at their body weight achieved at the end of 10 weeks ER.

To summarize, for the longer term, the imposed level of ER in man should in ar case be lower than 30%. A level of 10% seemed to be more feasible for the longer term but did not affect health parameters after 10 weeks. In addition, in stead of imposing fixed level of ER, stabilization at a body weight below one's body weight at 20-30 yea will most probably more feasible.

How can ER be achieved in man?:
Besides the uncertainty about the appropriate level that could be imposed in human which in any case should thus be lower than 30%, another question is how th restriction of energy intake could be achieved. Most designs of energy restriction studi in rodents involve limiting the intake of all or at least most food components at a certa moment in life. Therefore, decreasing 'overall' energy intake (i.e. eating less everything while maintaining the relative contributions of the macronutrients), using th habitual intake as the reference point, is an obvious way to reduce the energy intake man and has been imposed in the first study.

Initially, it was unclear whether retardation of the ageing process is due to t decreased energy intake or to a particular dietary component. Yet, animal studies hav convincingly demonstrated that the dietary factor in energy restriction studies responsib for the increase in life span and the retardation of the ageing process is the decrease energy intake per sé, irrespective of how ER was attained.[13] Reduction of the prote intake to the level of the dietary restricted rats did also increase longevity but le markedly than did dietary restriction.[14] However, the increase of longevity was related retarding nephropathy rather than influencing ageing processes as is the case with dieta restriction. Furthermore, decreasing the intake of fat or mineral components witho decreasing the intake of energy did not influence mortality characteristics of the rats.[15]

Energy percentage derived from fat is higher than recommended in most weste countries. Several studies have indicated that a high-fat diet is accompanied by a hi energy intake.[16,17] The body has limited ability to oxidize fat compared with its ability oxidize carbohydrate and protein. It has been suggested that the RQ (respirato quotient; CO_2 produced/O_2 consumed) is higher than the FQ (food quotient) while usi high carbohydrate/low fat diets, which indicates that the subject is mobilizing body fat Thus, as the energy intake itself is responsible for the anti-ageing effect and fat inta should be reduced, another option is to reduce the energy intake by decreasing dieta fat intake. The availability of reduced fat products has increased during the la decennium and consumption of these products might be a convenient way to reduce t energy intake in 'free living' situation. Therefore, in the second study, the MSFA study, the potential of reduced fat products to reduce the energy intake, and its effe on general health was studied. As described in Chapter 9 and 10, consumption

reduced fat products did not reduce the energy intake as compared to baseline values. However, as compared to the control group a significant difference in energy intake as well as in percentage energy intake derived from fat has been found. At least, considering the entire study population (n = 120), ad libitum consumption of these products prevented the overconsumption of energy and dietary fat since subjects in the control group gained 1 kg on average, while subjects in the reduced fat group remained weight stable. The difference in the change in body fat (0.61 kg) nearly reached significance. Nevertheless, since a difference in energy intake has been achieved between the control group, receiving full-fat products, and the reduced-fat group it might be concluded that macronutrient composition plays a role in energy intake.

This thesis was based on the concept that any level of energy intake below the habitual energy intake of a subject with a stable weight is a certain form of ER. However, ER can be induced in different ways. Energy intake is one side of the energy balance, the other side is energy expenditure. A topic not addressed to in this thesis, but not less interesting, is the role of exercise in increasing health and longevity. Hollozy[19,20] found that voluntary exercise on activity wheels in rats increased the mean but, in contrast to energy restricted controls of the same weight, did not result in an extension of the maximum length of life. When energy intake in wheel running rats was increased such that runners and sedentary control rats attained similar peak body weights, runners showed a significant prolongation of average longevity.[21] In humans there seems to be no indication that there is a relation between a history of athletic status and longevity.[22,23] However, mean life expectancy has reported to be higher in Finnish team members in intercountry games than in a reference group. This increase in life expectancy was mainly explained by decreased cardiovascular mortality. In addition, no difference in maximum life span between groups was observed.[24] Similar results are obtained in a Dutch study which showed that the mortality ratio in a group of recreational participants in the Dutch eleven cities ice skating tour (200 km) was significantly lower than that in the general population in the Netherlands, which lead to the conclusion that the capacity for prolonged and vigorous physical exercise, particularly if it is recreational, is a indicator of longevity.[25] Although it can not be excluded that these studies are biased by the fact that only 'stronger' subjects are capable in exercising regularly, these studies in man suggest that exercise might at least prolong mean life span, comparable to the findings in rodents mentioned above. Exercise as such has beneficial effects on cardiovascular function, lipoprotein risk factors for CHD, and has a preventive effect on diabetes and bone mineral loss,[26] and thus increases health-span.

HEALTH RISKS/BENEFITS OF ENERGY RESTRICTION

Introduction of an energy restricted diet in healthy non-obese subjects may result
health benefits but also in health risks. For example, too much weight loss resulting
decreased capacity for physical and mental performance should be avoided. Als
extreme hunger feelings and immune dysfunction might be undesirable side effects
imposed ER. On the other hand, high quality food intake resulting in gradual weig
loss, may be expected to yield a number of health benefits even if life span is n
extended. Rowe and Kahn[27] have made a differentiated 'usual' and 'successful' agein;
age-related changes such as increases in blood pressure, serum cholesterol levels an
bone loss are considered as physiologic. However, those who demonstrate little or n
loss in a constellation of physiologic functions have aged successfully.

The results of our first study, described in this thesis in Chapter 3-6 revealed th
at 10 weeks of energy restriction under dietary controlled conditions no significa
changes in hunger and satiety or in obvious health risks were observed. On the contrar
the imposed level of ER, approximately 30%, seemed to act beneficially on bloo
pressure and lipid profile (Chapter 3), as well as on fibrinolytic factors in those subjec
with initially high PAI-1 activity levels (Chapter 6). In Chapter 4 it has been conclude
that 10 weeks of 'moderate' ER lead to a slight but significant decrease in maxim
power output when compared to the change in the control group, measured with
bicycle ergometer. The decrease of 6.3 Watt in maximal output in the ER grou
represented a decrease of only 2.5%, and was not significantly different from zero. I
addition, this decrease in maximal power output was not related to the amount of weig
loss. This observation is in agreement with the finding that aerobic power was n
changed,[28] or even improved,[29] after a period of VLCD resulting in considerable amoun
of weight loss.

Results from the MSFAT-study showed that the difference in energy intake and th
difference in percentage energy derived from fat, induced by long-term consumption o
reduced fat products, did not beneficially nor adversely affect lipid profile, immun
status parameters,[30] fibrinolytic factors or outcomes of the oral glucose tolerance te
(Chapter 9).

Thus, apart from a potential life extending effect of ER, the results of the fir
study studies show that short-term energy restriction, resulting in 10% body weight los
and a final BMI of 22.6 kg/m², beneficially affects general health parameters bloo
pressure, lipid profile and fibrinolytic factors, even in non-obese men. Whether thes
effects could be maintained after the subjects had stabilized at their new body weig
requires further investigation. The results of the MSFAT study showed that consumptio
of reduced fat intake lowers percentage energy derived from fat to the recommende

level of 30-35 en%. As a high fat intake is related to the high prevalence of cardiovascular diseases, obesity and cancer, consumption of reduced fat products might have a potential to maintain health.

THE UNDERLYING MECHANISM OF THE BENEFICIAL EFFECTS OF ENERGY RESTRICTION

Several possible mechanisms through which ER modulates the ageing process have been suggested. As described in Chapter 1, free radical reactions are considered to play an important role in the ageing process and have been related to the progressive accumulation of age-related degenerative changes. Harman[31] formulated his 'free radical theory of ageing' as early as in 1954, in which he postulated that ageing might be attributed at least in part to accumulative damage caused by radical generation associated with cellular metabolic activity. In line with this suggestion a negative correlation between age and SOD activity was found in the MSFAT study (Chapter 10). However, the relevance of this finding is not clear, since on the basis of Harman's theory more correlations between age and free radical damage or free radical scavenging capacity could be expected.

ER and oxidative stress:
Energy restriction seems to improve, or at least maintain, the balance between prooxidants and antioxidants, leading to reduced free radical damage during ageing in rodents by lowering the free radical production rate and/or by enhancing the free radical scavenging capacity (Chapter 1). As this observation has received much attention lately, we investigated whether short-term ER and consumption of reduced fat product affects free radical scavenging capacity and damage in humans. However, no effect of 10 weeks ER or 6 months consumption of reduced fat products on selected parameters of plasma antioxidative vitamins, erythrocyte free radical scavenging enzyme activities nor the plasma lipid peroxidation product malondialdehyde could be demonstrated (Chapter 7 and Chapter 10 respectively). Ten weeks of ER did not affect urinary or lymphocyte 8OHdG concentration and selected parameters of genotoxicity either (Chapter 7). Possible reasons for not finding an effect are discussed in these chapters. Briefly, the reasons mentioned are: 1) free radical damage may be less in humans because of a relatively lower metabolic rate. As a consequence, they might benefit less from ER than species with a high metabolic rate; 2) the differences achieved might have been too small to detect changes or correlations between (changes in) parameters, 3) the period studied might have been too short, 4) the antioxidant/prooxidant balance might be rather

stable in the age category used in this study and 5) an important reason for not findin
changes in the parameters of oxidative stress and antioxidative capacity might be th
type of biomarker used. It can be argued that finding no effects on a peripheral lev
does not exclude that changes have occurred on a cellular level. Nevertheless, due to on
(or a combination) of these factors average levels of the parameters related to th
prooxidant/antioxidant balance were not affected by 10 weeks of ER nor by 6 month
consumption of reduced fat products.

Metabolic rate and oxidative stress:

According to Harman's theory, free-radical damage can by reduced by lowerin
metabolic rate. This suggestion has been supported by studies from Cutler[32] who showe
an inverse relationship between species-specific life span and metabolic rate. Howeve
in contrast to Cutler, we studied relationships within one species. Our results do n
indicate that the parameters measured would change with decreased metabolic rate. Suc
a change could be expected on the basis of Sacher's[33] suggestion that ER reduce
metabolic rate and thereby retards the ageing process. In line with Cutler's[32] 'rate c
living theory' calculated BMR (based on kg fat-free mass and kg fat mass) and GSH-P
activity were inversely related (Chapter 10). However, this relationship was only foun
in the MSFAT-study, but not in the first study, probably due to the small number c
subjects. To which extent this apparent relationship between BMR and GSH-Px activit
is observed by chance, remains uncertain. If a relationship between metabolic rate an
free radical damage within a species exists, one would expect to find correlation
between BMR and at least some of the other parameters such as plasm
malondialdehyde (MDA) concentration, erythrocyte superoxide dismutase (SOD
activity, etc. as well. Further (epidemiological) studies are needed in order to confirm
this relationship.

Free radical damage and free radical scavenging capacity in humans can only b
measured using 'indirect' measurements. By measuring free radical scavenging enzyme:
antioxidative enzymes as well as radical damage such as lipid peroxidation product
(MDA) and DNA-adducts it was tried to evaluate both aspects and to complete th
picture as much as possible. However, a good marker for oxidative stress is still lacking

CONCLUSION

From the studies described in this thesis it appears that 30% ER is not an acceptable strategy for the longer term. However, this level of ER resulted after 10 weeks in 10% weight loss, a final BMI of 22.6 kg/m² on average and beneficially affected several health status parameters. A mild level of ER, i.e approximately 10%, seems to be more feasible but did not result in positive changes in health parameters after 10 weeks. Consumption of reduced fat products under 'free living conditions' did reduce the percentage derived from fat to the recommended level but did not reduce the energy intake when compared to baseline values. However, energy intake was significantly lower during consumption of reduced fat products as compared to consumption of the full-fat equivalents. From these results it can be concluded that at present a feasible level of ER may be hard to implement as a long-term intervention under free living conditions. Moreover, short-term effects of ER in our study did not confirm the finding in animals that ER beneficially affects the prooxidant/antioxidant balance. Thus, if one succeeds in maintaining a energy restricted diet the beneficial effects, i.e. postponed ageing, remains to be established.

RECOMMENDATIONS FOR FUTURE RESEARCH

It would be too ambitious to expect this thesis to provide a final answer to the question whether ER will be applicable in man. However, on the basis of the results presented in this thesis some recommendations can be made for future research.

The Level of ER:
- Since 10 weeks of ER, resulting in 10% weight loss on average, seems to affect several 'health-parameters' beneficially. It would be interesting to investigate whether such a positive effect can be maintained over a longer period after stabilization on this new body weight.
- This 10% weight reduction seemed to be an acceptable level for the short term. However, what level of weight reduction will be optimal in terms of acceptability and health for the long term remains to be studied.
- At the population level it will most probably be more convenient to strive after an optimal body mass index in stead of an optimal body composition. An intriguing questions remains whether an 'optimal' BMI can be defined in terms of maximal life and health span. Data available up to now show a J- or U-shaped curve between BMI and mortality.[34] However, this relationship seems to be confounded by lean smokers

and pre-existing illness or to represent only a subpopulation (7th-day adventists vegetarians). Studies in which these confounders are controlled for are recommended.

- Recently, is has been reported that weight changes (i.e. both weight loss and weight gain) of 1-5 kg, independent of BMI, are associated with significantly increased mortality.[35] In addition, weight cycling appears to correlate positively with waist-hip ratio,[36] which in turn has been associated with increased mortality.[37] These data do not imply that obese persons should remain obese, but this might imply that ER should be applied at least in order to prevent the usual weight gain during ageing. Again, the relationship between weight loss and mortality might be confounded by pre-existing illness. Therefore, more research into the relationship between weight change and mortality is needed.

Achievement:

- Since consumption of reduced fat products resulted in significantly lower energy intake as compared to consumption of full-fat equivalents, it would still be interesting to investigate whether longer term consumption of reduced fat products reduces the energy intake.
- Another approach which remains to be studied is whether long term consumption of artificially sweetened products, whether or not in combination with reduced fat products, reduces the habitual energy intake.
- Since the use of dietary fibre has been suggested to have an impact on satiety,[38] it seems also worthwhile to investigate its potential for reducing the energy intake.

Biomarkers of ageing:

- Ageing research is complicated by the lack of a suitable 'biomarker of ageing'. The development of such a biomarkers is urgently needed. Such biomarkers should 1) be measurable without health risks for the subject, 2) be highly reproducible and reflect physiological age, i.e. status of physiological functions with respect to subjects chronological age (years), 3) show significant age changes within a relatively brief time period and 4) the clinical functions should be crucial to the health of species. As discussed in Chapter 7 the fact that most of the evidence of the anti-ageing effect of ER on free radical reactions and oxidative stress in animal studies is based upon findings obtained from organ tissues, especially liver, complicates a comparison between human and animal data. Studies in man are limited to the substrates readily available for analysis such as blood and urine samples.

Energy restriction (ER), while maintaining the intake of adequate amounts of essential nutrients, retards the ageing process and extends life span in various animal species. Although several potential mechanisms have been put forward, the mechanism behind this phenomenon remains unknown. The literature on the effects of ER on three physiological processes related to ageing, i.e. adaptation of energy metabolism, free radical reactions and antioxidative capacity, and the endocrine system have been reviewed in Chapter 1. From this review it has been concluded that:

1) in both animals and man severe energy restriction lowers the resting metabolic rate (RMR), expressed in absolute terms. Long-term energy restriction, for example in undernourished labourers and anorexia nervosa patients, decreases the activity of metabolic tissue and probably increases metabolic efficiency, since in these studies RMR expressed per kg fat-free mass was found to be reduced;

2) in animals, a decrease in the activity of free radical scavenging enzymes with increasing age has been found. ER, however, seems to maintain and/or improve protection against free radical damage in these animals, which may play a role in the life-prolonging effect. However, data on the effects of ageing and ER on damage due to free radicals or free radical scavenging capacity in man are absent; and

3) ageing affects the hormonal system in both animals and man which is manifested in dysfunction of the sympathetic nervous system, decreased T4 concentrations, decreased secretion of gonadotropic hormones, and decreased glucose tolerance. This can be a result of 'wear and tear' with advancing age. ER prevents the decrease in T4, testosterone and LH which provides evidence for the hypothesis that ER maintains the functional integrity of the neuroendocrine system.

There certainly are quantitative differences in metabolism between animals and men. However, with regard to these three physiological processes, neither the effects of ER nor the age related changes seemed to differ between animals and man. From this point of view, ER might have a beneficial effect on the ageing process in man as well. However, little is known regarding the applicability of ER as an intervention to retard human ageing. Moreover, the life-long animal studies are hard, of not impossible, to mimic in interventions in humans.

A prerequisite before studying potential age-retardation effects in humans is to study the potential of implementation of an ER-diet tenable for the longer term, as well as to investigate potential health risks or benefits of ER. Therefore, this project was started with a 10-week intervention study in order to investigate the applicability as well as potential health benefits or risks of a moderate energy restricted diet, aimed to contain 80% of the energy of reported intake (20% ER), assessed by means of a 7-day dietary record. The

results of this study, performed in 24 healthy middle-age men (range 35-50 yr) ar described in Chapter 3-7. Weight loss was considerable in the ER group (-7.4 ± 2.6 kg n = 16), and there was no tendency for stabilization on a new energy balance. Subjects i the control group, lost some weight too (-2.7 ± 2.1 kg; n = 8). This study showed that thi ten weeks of ER had beneficial effects on blood pressure and HDL-cholestero concentration, without having adverse effects on physical and mental performance, an feelings of hunger, satiety and mood (Chapter 3). The effects on physical performance ar further elaborated in Chapter 4. Maximal power output showed a slight decreas (-6.3 ± 13.6 Watt), which appeared to be significant (P = 0.049) when compared to th change in the control group (4.3 ± 5.9 Watt). However, this decrease was not related to th decrease in body weight. In addition, no effects of ER on substrate utilization durin submaximal exercise were observed. Chapter 5 describes the effects of ER on energ metabolism and body composition in these 24 subjects. By making use of the doubl labelled water technique in 8 subjects of the ER group it appeared that reported energ intake was 82.5% of total energy expenditure (ADMR = average daily metabolic rate resulting in an actual level of ER of 33%, rather than 20%. Furthermore, in the ER grou 83% of the weight loss was fat mass, 17% was fat-free mass. ADMR decrease significantly. Resting metabolic rate decreased in the ER group, even when taking int account the decrease of fat-free mass.In addition, the plasma concentration of the thyroi hormone T3 decreased, while reverse T3 concentration showed an increase. Another healt aspect that can be affected by ER is the haemostatic system. From the results presented i Chapter 6, is can be concluded that ER lead to decreased plasminogen activator inhibito type 1 (PAI-1) antigen concentration, as well as to decreased tissue-type plasminoge activator (tPA) antigen concentration. These changes were more clear in those subjects wit a high baseline PAI activity (> 9 IU/ml). As a high concentration of PAI-1 antigen has bee associated with an increased risk for coronary thrombosis, these findings suggest that E beneficially affects fibrinolytic factors, at least in subjects with higher baseline PAI activit

The beneficial effects of ER on the ageing process has been hypothesized to proceed b lowering the production rate of free radicals (probably secondary to a lower metabolic rate and/or by the maintenance of (or enhancing) effective scavenging capacity of free radical Therefore, the effects of 10 weeks ER on the primary antioxidant defence system measure by the antioxidant enzymes superoxide dismutase (SOD), glutathione peroxidase (GSH-Px and catalase, as well as on the antioxidant vitamins C, E, A and β-carotene was assesse In addition, oxidative damage, measured by the lipid peroxidation product malondialdehyd (MDA), and the DNA-adduct 8-hydroxydeoxyguanosine (8OHdG), low-density lipoprotei resistance of in-vitro copper mediated oxidation, and markers of genotoxicity were als investigated. (Chapter 7). None of these parameters were found to be affected by 10 week

of ER. However, this result does not exclude that ER affects the antioxidant/prooxidant balance on the cellular level, nor that these parameters would not be affected by ER on the longer-term.

This first study was performed under strictly dietary controlled conditions and does not provide information about the feasibility to reduce the energy intake under 'free living' conditions. Therefore, a second study was executed under 'free living conditions' in which the potential of reduced-fat products to reduce the energy intake was investigated. This study was part of a multi-centre study, the MSFAT-study (i.e. Multicentre Study on FAT reduction), on the health effects of consumption of reduced fat products. The control and reduced-fat products were provided through a realistic shop in order to mimic a 'free living' situation. The design of this 6 month parallel comparison trial has been described extensively in Chapter 8. In the MSFAT-study the same parameters as in the first study were measured. Realistic consumption of reduced-fat products lead to a significantly lower energy intake as well as to lower percentage of energy derived from dietary fat as compared to consumption of full-fat equivalents. However, this did not result in a change in the coronary heart disease risk markers PAI-1 antigen, tPA activity, fibrinogen concentration, factor VII concentration and insulin sensitivity (Chapter 9). Since both energy restriction as well as dietary fat intake might affect the antioxidative capacity, again, parameters that reflect the antioxidant/prooxidant balance (plasma MDA, antioxidative vitamins lycopene, β-carotene and α-tocopherol, and erythrocyte free radical scavenging enzymes SOD, GSH-Px and catalase) were measured (Chapter 10). The results indicate that neither the difference in energy intake, nor the decrease in vitamin E intake and a change in dietary acid composition seemed to affect the prooxidant/antioxidant balance.

The results of these two studies are discussed in Chapter 11 in view of the following questions:
- What is the potential of implementation of an ER-diet tenable for the longer term?
  - what level of ER will be appropriate for the long term?
  - how can an ER-diet, acceptable for the long term, be achieved in man?
- Does ER result in health benefits and/or health risks?
- Does short-term ER affect the antioxidant/prooxidant balance, a potential underlying mechanism of the beneficial effects of ER, in man?

It has been concluded that from the studies described in this thesis it appears that 30% ER is not an acceptable longer-term strategy. This level of ER resulted in 10% weight loss, a final BMI of 22.6 kg/m^2 on average and beneficially affected several health status parameters. A mild level of ER, i.e. approximately 10%, seems to be more feasible but this did not result in changes in health parameters after 10 weeks, as can be assessed on the

basis of the control group who were mildly restricted in their energy intake due t
underreporting. Consumption of reduced fat products under 'free living conditions' di
reduce the percentage energy derived from fat to the recommended level but did not reduc
the energy intake when compared to baseline levels. However, energy intake wa
significantly lower during consumption of reduced fat products as compared to consumptio
of the full-fat equivalents. From these results it can be concluded that a feasible level of El
seems hard to implement as a long-term intervention under free living conditions. Howeve
short-term effects of ER beneficially affected several health-status parameters which migh
at least affect the 'health'-span if these changes can be maintained for the longer term. Ou
study did not support the finding in animals that ER beneficially affects th
prooxidant/antioxidant balance. However, whether the prooxidant/antioxidant balance woul
be affected by longer term ER, or in older subjects, needs further investigation.

Beperking van de energie inneming (energie restrictie; ER), bij een adequate voorziening van essentiële nutriënten, vertraagt het verouderingsproces en verlengt de maximale levensduur bij verschillende soorten proefdieren. Ondanks dat er verschillende suggesties zijn gedaan is het onderliggende mechanisme nog steeds niet opgehelderd. De literatuur met betrekking tot de effecten van ER op drie fysiologische systemen die mogelijk gerelateerd zijn aan het verouderingsproces (verandering van het energie metabolisme, reacties door vrije radicalen en antioxidatieve capaciteit, en het neuro-endocriene systeem) zijn samengevat in Hoofdstuk 1. Uit de in dit hoofdstuk besproken literatuur kan het volgende worden geconcludeerd:

1) bij zowel proefdieren als de mens leidt strenge energie restrictie tot een verlaging van de ruststofwisseling, uitgedrukt als kJ per dag. Lange termijn ER, zoals bijvoorbeeld beschreven bij een groep ondervoede arbeiders of bij anorexia nervosa patiënten, resulteert eveneens in een afname van de metabole snelheid, en waarschijnlijk ook tot een verhoogde metabole efficiëntie omdat bij deze mensen ook de ruststofwisseling uitgedrukt als kJ per kg vet-vrije massa (= metabool actieve massa) verlaagd is.

2) bij proefdieren lijkt de activiteit van enzymen die vrij-radicalen neutraliseren gedurende het verouderingsproces af te nemen. Bij beperking van de energie inneming lijkt echter de vrij-radicaal opvangcapaciteit langer gehandhaafd of zelfs verbeterd waardoor minder schadeprodukten ontstaan, hetgeen een rol zou kunnen spelen bij het vertragen van het verouderingsproces. Helaas zijn er nauwelijks gegevens bekend over de effecten van ER en veroudering bij de mens enerzijds en vrij-radicaal schade en opvangcapaciteit anderzijds.

3) de verandering van het neuro-endocriene systeem gedurende het verouderingsproces uit zich in een verminderde functie van het sympatisch zenuwstelsel, afname van het schildklier hormoon thyroxine (T4), afname van de geslachtshormonen, en een verminderde glucose tolerantie. ER voorkomt de afname van T4, het mannelijke geslachtshormoon testosteron en het vrouwelijke geslachtshormoon luteïniserings-hormoon (LH). Dit fenomeen bevestigt de hypothese dat ER de functionele integriteit van het hormonale systeem handhaaft.

Hoewel er weliswaar kwantitatieve verschillen zijn in het metabolisme tussen dier en mens, lijkt het niet aannemelijk dat, ten opzichte van de bovengenoemde fysiologische systemen, het effect van veroudering of ER verschilt tussen mens en dier. Om deze reden zou ER ook het verouderingsproces bij de mens kunnen vertragen. Er is echter tot nu toe weinig onderzoek gedaan naar de toepasbaarheid van ER als een interventie bij de mens om het verouderingsproces te vertragen. Daarnaast zijn er helaas nauwelijks gegevens over de effecten van ER op het verouderingsproces bij de mens, noch over de accumulatie van schadeprodukten, noch over de vrij-radicaal opvangcapaciteit.

Een noodzakelijke voorwaarde om de mogelijke verouderingseffecten bij de mens ⸀
onderzoeken, is het bestuderen van de mogelijkheden om bij de mens een aanvaardbar
energiebeperkte voeding te introduceren, en om hierbij te kijken naar eventuel
gezondheidsrisico's of -winst. Het in dit proefschrift beschreven onderzoek werd daaro
gestart met een 12 weken durende studie (2 weken inloopperiode; 10 weken interventie) oi
zowel de toepasbaarheid als eventuele gezondheidseffecten van een matige energiebeperkir
te bestuderen. Het niveau van energie inneming was gericht op 80% van de gebruikelijk
energie inneming (20% ER), welke geschat was op basis van de 7-daagse opschrijfmethod
De resultaten van deze studie, uitgevoerd bij 24 gezonde mannen (35-50 jaar) zij
beschreven in de Hoofdstukken 3 t/m 7. Het gewichtsverlies in de ER groep gedurende ⸀
10 weken was aanzienlijk (-7.4 ± 2.6 kg; n=16), en er was geen tendens t
gewichtsstabilisatie. De proefpersonen in de controle groep verloren ook wat gewic
(-2.7 ± 2.1 kg; n=8). Tien weken ER had een gunstig effect op de bloeddruk en ⸀
HDL-cholesterol concentratie, terwijl er geen negatieve effecten te zien waren op fysiek ⸀
mentaal prestatievermogen, en gevoelens van honger en verzadiging en stemmir
(Hoofdstuk 3). Het effect op het fysiek prestatievermogen is uitgebreid beschreven
Hoofdstuk 4. Het maximale prestatievermogen nam in de ER groep af (-6.3 ± 13.6 Wat
deze verandering was significant verschillend van die in de controle groep (4.3 ± 5.9 Wat
Echter, de daling in maximaal prestatievermogen was niet gerelateerd aan h
gewichtsverlies. Het substraatgebruik tijdens submaximale inspanning veranderde niet do
ER. Hoofdstuk 5 beschrijft het effect van ER op energiemetabolisme ⸀
lichaamssamenstelling in deze 24 mensen. Door gebruik te maken van tweevoudig gemer
water is bij 8 proefpersonen in de ER groep het totale energiegebruik gemeten. Uit de
meting bleek dat de gerapporteerde energie inneming slechts 82.5% van het tota
energiegebruik gedurende de inloopperiode bedroeg. Als gevolg van deze onderrapportaį
was de opgelegde ER geen 20% maar 33%. Het gewichtsverlies in de ER groep bleek voi
ca. 83% uit verlies aan vet-massa en voor ca. 17% uit vet-vrije massa. Het tota
energiegebruik daalde significant evenals de ruststofwisseling, ook wanneer de laat:
gecorrigeerd werd voor de verandering in vet-vrije massa. De plasmaconcentratie van ł
schildklierhormoon T3 vertoonde een significante daling, terwijl de concentratie van ł
reverse-T3 een stijging vertoonde. Een ander gezondheidsaspect dat werd bestudeerd is
haemostase. Uit de resultaten weergegeven in Hoofdstuk 6 kan worden geconcludeerd ⸀
ER leidde tot een afname in de plasminogeen activator inhibitor type 1 (PAI-1) antig
concentratie en in de weefseltype plasminogeen activator (tPA) antigen concentratie. De
verandering was het meest uitgesproken in personen die bij aanvang van de studie een ho
PAI activiteit (> 9 IU/ml) hadden. Omdat een hoge PAI-1 antigen concentratie als e
risicofactor voor coronaire hartziekten wordt beschouwd, suggereren deze resultaten dat ł
een gunstig effect heeft op fibrinolysefactoren bij personen met een hoge PAI activiteit

Een hypothese om het gunstige effect van ER op het verouderingsproces te verklaren is dat dit effect gemedieerd wordt door verlaging van de produktie van vrije radicalen, secundair aan een verlaagd metabolisme, en/of door handhaving (of verbetering) van de opvangcapaciteit van vrije radicalen. Daarom werd het effect van 10 weken ER op het primaire antioxidant systeem onderzocht, i.e. zowel de activiteit van de antioxidant enzymen in erythrocyten (superoxide dismutase, SOD; glutathion peroxidase, GSH-Px; en catalase) als de concentraties van antioxidant vitaminen in plasma (C, A, E en β-caroteen). Daarnaast werden oxidative schadeprodukten zoals het lipid peroxidatie produkt malondialdehyde (MDA) en het DNA-adduct 8-hydroxydeoxyguanosine (8OHdG) gemeten, en werden genotoxiciteits-markers en de oxideerbaarheid van het low density lipoproteïne bepaald. Geen van deze parameters veranderden onder invloed van 10 weken ER (Hoofdstuk 7). Deze resultaten sluiten echter niet uit dat er geen verandering in de prooxidant/antioxidant balans heeft plaatsgevonden op cellulair niveau, of dat de gemeten parameters niet beïnvloedt worden na lange termijn ER.

Deze eerste studie werd uitgevoerd onder streng gecontroleerde omstandigheden en geeft daarom geen informatie over de toepasbaarheid van ER in een 'vrij-levende' situatie. Daarom werd een tweede studie uitgevoerd als onderdeel van de MSFAT-studie (Multi-center Studie naar vet (fat) reductie), een studie naar de gezondheidseffecten van laag-vet produkten. De controle (vol-vet) produkten en de laag-vet produkten werden verstrekt via een speciaal hiervoor ingerichte winkel. De opzet van deze 6 maanden durende studie is beschreven in Hoofdstuk 8. In de MSFAT-studie werden dezelfde parameters gemeten als in de eerste studie dat beschreven is in dit proefschrift. Consumptie van laag-vet produkten leidde tot een significant lagere energie inneming en een lagere bijdrage van vet aan energie in vergelijking met consumptie van de vol-vet controle produkten. Echter, dit resulteerde niet in een verandering in gemeten risicofactoren voor hart- en vaatziekten, PAI-1 antigen, tPA activiteit, fibrinogeen concentratie, Factor VII concentratie en insuline gevoeligheid (Hoofdstuk 9). Omdat zowel energiebeperking als vetzuursamenstelling in de voeding de antioxidant status kunnen beïnvloeden werd ook in deze studie een aantal parameters bepaald die betrekking hebben op de antioxidant/prooxidant balans (plasma MDA, de antioxidanten lycopeen, β-caroteen en α-tocopherol, en antioxidant enzymen SOD, GSH-Px en catalase in erythrocyten) gemeten. Op basis van de resultaten werd geconcludeerd dat noch het verschil in energie inneming, noch de afname in vitamine E inneming noch de verandering in vetzuursamenstelling in de voeding de prooxidant/antioxidant balans beïnvloeden (Hoofdstuk 10).

De resultaten van deze twee studies worden bediscussieerd in Hoofdstuk 11 aan de hand van de volgende onderzoeksvragen:

- Wat is de mogelijkheid om een energiebeperkt dieet bij de mens te introducere zodanig dat het aanvaardbaar is voor de lange termijn?
  - welk niveau van ER kan gedurende lange tijd volgehouden worden?
  - hoe kan een aanvaardbaar niveau van ER bereikt worden bij de mens?
- Resulteert ER in gezondheidsrisico's of gezondheidswinst?
- Beïnvloedt ER de antioxidant/prooxidant balans, en worden de gunstige effecten va ER op het verouderingsproces via dit systeem gemedieerd?

Uit de studies beschreven in dit proefschrift kan worden geconcludeerd dat 30% ER in ied geval geen acceptabele en na te streven optie is voor de lange termijn omdat stabilisatie o een nieuw energiebalans onrealistisch lijkt. Dit niveau van ER resulteerde na 10 weken i gemiddeld 10% gewichtsverlies en een Body Mass Index (BMI) van 22.6 kg/m^2. W werden op korte termijn verschillende gezondheidsparameters gunstig beïnvloedt. Kor termijn ER zou daarom de 'gezondheidsduur' kunnen verlengen indien deze veranderinge gehandhaafd blijven voor de lange termijn nadat de proefpersonen gestabiliseerd zoude worden op de aan het eind van de 10 weken bereikte BMI. De controle groep ondergi als gevolg van onderrapportage een milde vorm van energie beperking. Deze milde energi beperking, ca. 10% ER, lijkt voor de langere termijn meer acceptabel, maar leidde op kor termijn niet tot veranderingen in gezondheidsparameters.

Door consumptie van laag-vet produkten onder 'vrij-levende' omstandigheden wer het percentage energie uit vet verlaagd tot een aanbevolen hoeveelheid, maar de energi inneming werd niet lager in vergelijking met de uitgangswaarden. Echter, de energi inneming was wel lager in de groep die laag-vet produkten consumeerden dan in de groe die de overeenkomstige produkten met een hoog-vet gehalte consumeerden.

Uit deze twee studies kan worden geconcludeerd dat een aanvaardbaar niveau van E moeilijk is vast te stellen en als een lange termijn interventie te implementeren ond vrij-levende condities met als doel het verouderingsproces te vertragen. Onze studi bevestigden niet de bevinding bij dieren dat ER de prooxidant/antioxidant balans gunst beïnvloedt. Of deze balans wel te beïnvloeden is door lange termijn ER of in oude proefpersonen vereist nader onderzoek.

Het schrijven van dit hoofdstuk betekent eveneens terugkijken op een periode bij TNO-Voeding waar ik met veel plezier heb gewerkt. Het maakt me ook bewust van het feit dat veel mensen hebben meegewerkt aan de tot stand koming van dit boekje. Een aantal van hen wil ik hier met name noemen.

Veel dank ben ik verschuldigd aan mijn co-promotor Henk van den Berg. Henk, wij konden het samen meestal goed vinden, wat er mede voor zorgde dat de afgelopen vier jaar zijn omgevlogen. Jouw vertrouwen in mijn werk en de adviezen en kritische kanttekeningen op de manuscripten heb ik erg gewaardeerd.
Dank ook aan mijn tweede co-promotor Klaas Westerterp. Klaas, jouw snelle en efficiënte wijze waarop je reageerde op mijn brieven en telefoontjes werkte stimulerend en heb ik erg op prijs gesteld.
Mijn promotoren Wim Saris en Ruud Hermus wil ik bedanken voor de zinvolle suggesties op met name de inleiding en de discussie van dit proefschrift. Wim Saris wil ik tevens bedanken voor zijn rol als eerste promotor.

Gertjan Schaafsma, jij hebt je altijd ingezet voor mijn belangen, en aan jou heb ik mede te danken dat ik na mijn stage-periode deze promotieplaats heb mogen vervullen.

Anneke Engelgeer-Bekius was onmisbaar bij het uitvoeren van de MSFAT-studie. Anneke, jij hebt ten behoeve van de MSFAT-study heel wat vrieskou ($-20°$C) doorstaan, in ca. 600 huidplooien geknepen en ca. 300 eetdagboekjes doorgenomen. De hoeveelheid pizza's en kant-en-klaar maaltijden die je met een karretje door regen en sneeuw moest vervoeren is echter ontelbaar. Anneke, hartelijk dank voor de fijne samenwerking en voor het feit dat je nu de taak van paranimf op je wilt nemen.

Petra van Aken-Schneijder en Ann Colen, bij jullie kon ik terecht voor de diëtetistische en huishoudkundige ondersteuning en voor praktische tips bij het uitvoeren van de studies. Bedankt hiervoor.

Twee stagiaires bewegingswetenschappen van de Vrije Universiteit Amsterdam hebben een belangrijk aandeel geleverd in het afnemen van de fysieke inspanningstesten bij de vrijwilligers. Wieke Hoogzaad en Marleen van der Horst, dank jullie wel!
Helga Peeters wil ik bedanken voor haar aandeel als stagiaire Gezondheids-wetenschappen in de analyse van malondialdehyde.

Van de divisie Pharma wil ik Wilfred Sieling, Theo Hoofwijk en Jaap Odink graa
bedanken voor hun hulp bij praktische uitvoer van de studies. Jan Catburg en zij
medewerkers dank ik voor het uitvoeren van alle klinisch-chemische analyses. Verde
dank ik alle analisten die betrokken zijn geweest bij de vitamine analyses, radic
immunologische bepalingen, genotoxiciteits bepalingen en de immunologische analyses.

Naast de analyses die gedaan zijn bij TNO-Voeding in Zeist is er buiten de deur ook h
één en ander bepaald. De medewerkers van het Gaubius Instituut Leiden en va
TNO-PG Leiden wil ik danken voor de bepaling van de heamostase parameters en voc
de bepaling van de oxideerbaarheid van LDL, en van 8OHdG in lymfocyten. I woul
like to thank Steffen Loft and Henrik Poulsen from the University of Copenhagen fc
their cooperation and their analysis of 8OHdG excretion.

Dirk van der Heij, 'ome Dirk', belangstellend heb je de verschillende hoofdstukken i
dit proefschrift gelezen en voor engels-taligen leesbaarder gemaakt. Hartelijk dan
hiervoor. Niek van Breederode, bedankt voor het oplossen van mijn problemen di
betrekking hadden op vax-terminals, computers en printers. Jan Blom, bedankt voor h
kopieerwerk dat altijd 'even tussendoor' kon.

Hanny Leezer-de Hoog, jij heb meermalen in je avonduren dit proefschrift nagekeke
om de puntjes op de i te zetten. Het is ongelooflijk hoe je de tekst hebt doorgenome
om alle oneffenheden eruit te halen. Bedankt!

Alle (ex)collega's van TNO-Voeding die hier niet met naam zijn genoemd. Hartelij
dank voor de gezellige tijd! Ik zal jullie missen.

Zonder medewerking van proefpersonen had dit onderzoek nooit kunnen worde
uitgevoerd. Alle vrijwilligers die hebben meegedaan wil ik daarom bedanken voor hu
doorzettingsvermogen.

Mijn dank gaat ook uit naar de leden van de beoordelingscommissie: Prof. dr. F
Kuipers, Prof. dr. A. van Es, Dr. G. Hornstra, Prof. dr. D.L. Knook en Prof. dr. E.F.N
Wouters, voor het beoordeling van dit proefschrift.

Mijn ouders ben ik dankbaar voor de mogelijkheid en voor de stimulans die zij m
gaven om te studeren. Mijn zus Sylvia te Wierik wil ik bedanken voor de betrokkenhei
bij mijn werk en dat zij de taak van paranimf op zich wil nemen.
Tenslotte wil ik natuurlijk Paul bedanken voor al zijn steun.

Erica J.M. Velthuis-te Wierik werd geboren op 21 april 1967 te Raalte. In 1984 haalde zij haar HAVO diploma aan het Florens Radewijns College te Raalte. Aansluitend ging zij naar het VWO aan dezelfde school waarvoor zij in 1986 haar diploma kreeg. In datzelfde jaar begon zij haar studie Gezondheidswetenschappen, met als afstudeerrichting Biologische Gezondheidkunde aan de Rijksuniversiteit Limburg te Maastricht. Haar afstudeerstage met als onderwerp 'de invloed van matig alcoholgebruik op risicofactoren voor hart- en vaatziekten' deed zij van december 1989 tot en met augustus 1990 bij TNO-Voeding te Zeist, om in november 1990 haar doctoraal te behalen. Van oktober 1990 tot en met mei 1991 was zij in dienst van TNO om haar medewerking te verlenen voor het schrijven van een literatuuroverzicht wat resulteerde in het boek 'biomedical and social aspects of alcohol use, a review of the literature'. Per 1 juni 1991 trad zij in dienst als assistent in opleiding (A.I.O.) bij de Vakgroep Humane Biologie (Dr. K.R. Westerterp en Prof. dr. W.H.M. Saris) van de Rijksuniversiteit Limburg te Maastricht. Het onderzoek dat zij gedurende vier jaar verrichtte is echter uitgevoerd bij TNO-Voeding te Zeist (Dr. H. van den Berg en Prof. dr. ir. R.J.J. Hermus) en is beschreven in dit proefschrift. Sinds 1 mei 1995 is zij werkzaam als Scientific Editor bij N.V. Organon, een business unit van Akzo-Nobel.
