

A systematic review of the cost-effectiveness of worksite physical activity and/or nutrition programs

by Johanna M van Dongen, MSc,^{1,2,3} Karin I Proper, PhD,^{1,3} Marieke F van Wier, MSc,^{1,2,4} Allard J van der Beek, PhD,^{1,3} Paulien M Bongers, PhD,^{1,3,5} Willem van Mechelen, PhD,^{1,3} Maurits W van Tulder, PhD^{1,2,4}

van Dongen JM, Proper KI, van Wier MF, van der Beek AJ, Bongers PM, van Mechelen W, van Tulder MW. A systematic review of the cost-effectiveness of worksite physical activity and/or nutrition programs. *Scand J Work Environ Health*. 2012;38(5):393–408. doi:10.5271/sjweh.3275

Objective The aim of this study was to appraise and summarize the evidence on the cost-effectiveness of worksite physical activity and/or nutrition programs.

Methods We searched EMBASE, MEDLINE, SportDiscus, PsycInfo, NIOSHTIC-2, NHSEED, HTA, and Econlit for studies published up to 14 January 2011. Additionally, we searched for articles by reviewing references, searching authors' databases, and contacting authors of included studies. Two researchers independently selected articles. Articles had to include a cost-effectiveness and/or cost-utility analysis comparing a worksite physical activity and/or nutrition program to usual care or an abridged version of the program. Data were extracted on study characteristics and results. Two researchers independently assessed the risk of bias using the Consensus on Health Economic Criteria list (CHEC-list).

Results Ten studies (18 programs) were included. More than 50% of the studies fulfilled 11 (58%) of the 19 CHEC-list items. From various perspectives, worksite nutrition and worksite physical activity and nutrition programs (N=6) were more costly and more effective in reducing body weight than usual care. When only intervention costs were considered, most worksite nutrition (N=4/5) and worksite physical activity and nutrition programs (N=5/6) were more costly and more effective in reducing cholesterol level and cardiovascular disease risks, respectively.

Conclusions The cost-effectiveness of more costly and more effective programs depends on the “willingness to pay” for their effects. It is unknown how much decision-makers are willing to pay for reductions in body weight, cholesterol level, and cardiovascular disease risks. Therefore, conclusions about the cost-effectiveness of worksite physical activity and/or nutrition programs cannot be made. There is substantial need for improvement of the methodological quality of studies and particular emphasis should be placed on the handling of uncertainty.

Key terms dietary behavior; obesity; overweight; worksite health promotion.

Regular physical activity and healthy dietary habits are considered important in preventing overweight, obesity, and their attributable diseases [eg, diabetes type 2, cardiovascular disease (CVD) and certain cancers] (1–5). Nevertheless, many adults do not meet public health recommendations for nutrition and physical activity (6–11). Currently, 34% of United States (US) adults are overweight [body mass index (BMI) ≥ 25 kg/

m² and <30 kg/m²] and 34% are obese (BMI ≥ 30 kg/m) (12). In Europe, the combined prevalence of overweight and obesity ranges from 38–61% among women and 52–69% among men (13). In addition to the toll that overweight and obesity take on the health and well-being of individuals, they impose considerable financial burdens in terms of increased productivity-related and healthcare costs (14–16). Therefore, health promotion

programs aimed at increasing physical activity and/or improving nutrition are warranted.

The worksite provides a useful setting for implementing such programs; since employees spend up to 60% of their waking hours at the worksite, organizational and social support can easily be made available, and large enterprises often have the infrastructure to offer such program at relatively low costs (17–19). Employers themselves may also benefit from implementing worksite health promotion (WHP) programs, as healthier workers are expected to be more productive and miss fewer days of work (17).

WHP programs aimed at increasing physical activity and/or improving nutrition were found effective in reducing body fat and body weight (20–22). For example, a recent systematic review found worksite physical activity and nutrition programs to significantly reduce body weight by 1.2 kg, BMI by 0.3 kg/m², and body fat percentage by 1.1% during the first years after implementation (≤ 3 years) (22). Budgets for occupational healthcare are restricted. Decisions about investments in WHP programs may, therefore, not only be guided by the evidence on their effectiveness, but also by considerations of their costs in relation to these effects (23–25). For this reason, cost-effectiveness analyses (CEA) and cost-utility analyses (CUA) are conducted to gain insight into the (additional) costs of an intervention per additional unit of effect gained. These analyses not only give insight into the cost savings of an intervention, like return on investment (ROI) analyses, but also provide details on the price of achieving a particular goal if an intervention produces better outcomes at additional costs (eg, costs per kilogram body weight loss) (21).

Although ROI results are likely to be most frequently used within companies to describe the financial aspects of a business case for occupational health initiatives (26, 27), CEA may be of interest for corporate decision-makers as well. A recent systematic review on the financial return of worksite physical activity and/or nutrition programs indicated that they may not pay for themselves in terms of reduced medical and/or absenteeism costs during the first years after implementation (28). Nevertheless, a significant lag between health improvements and reductions in medical and/or productivity-related cost may exist. Therefore, reporting on cost-effectiveness in terms of intermediate outcome measures that might be associated with long-term cost savings (eg, body weight loss) (29), may also give useful information to aid implementation decisions (17). Furthermore, investments in WHP programs may be motivated not only by making a profit but also by obtaining positive health effects and/or by the wish to be a caring employer. In that case, their anticipated effects are worth having and the question is to determine the most cost-effective way to achieve it (ie, least costly per unit of effect) (30).

Up until now, various reviews have been conducted on the cost-effectiveness of WHP programs (20, 31–39). One of them (36), for example, concluded that the literature provided “guarded cautious optimism” about their cost-effectiveness. However, these reviews were limited to studies published up until 2008 and most of them looked at the cost-effectiveness of WHP programs in general (ie, also including disease and stress management, and smoking cessation programs), instead of worksite physical activity and/or nutrition programs in particular. Furthermore, although the quality of the design and execution of economic evaluations should be considered when judging the validity of their findings, none of the reviews used an internationally accepted instrument for assessing their risk of bias (40, 41). This raises questions about the credibility of their conclusions. Therefore, the aim of the present study was critically to appraise and summarize the current evidence on the immediate and long-term cost-effectiveness of worksite physical activity and/or nutrition programs compared to usual care or an abridged version of the program.

Methods

Search strategy

A systematic search was conducted to identify studies evaluating the cost-effectiveness and/or cost-utility of WHP programs aimed at improving nutrition and/or increasing physical activity. Eight databases (EMBASE, MEDLINE, SPORTDiscus, PsycINFO, NIOSHTIC-2, NHSEED, HTA, and Econlit) were searched for studies published up to 14 January 2011. An information specialist of the VU University Medical Center was consulted to develop and run the search strategy. Databases were searched with the following keywords: participant/setting type (eg, “Workplace”, “Employee”, “Workforce”), intervention type (eg, “Health Promotion”, “Lifestyle”), intervention aim (eg, “Exercise”, “Physical Activity”, “Nutrition”, and “Diet”), and study design (eg, “Cost-Effectiveness Analysis”, “Cost-Utility Analysis”, and “Economic Evaluation”). In addition to the present study, a systematic review on the financial return of worksite physical activity and/or nutrition programs was conducted (28). Therefore, a broad search strategy was used so that the search results could be used for both studies simultaneously.

As an example, the complete search strategy for EMBASE can be found in the Appendix. In addition to the electronic search, reference lists of relevant review articles (17, 18, 20, 21, 31–39, 42) and those of the retrieved fulltext were searched. Articles were also identified from the authors’ own literature databases. To

identify unpublished studies, authors of included studies published during the last decade were contacted. During the search, a “search diary” was maintained, including keywords used, searched databases, and search results.

Study selection

Titles and abstracts of retrieved studies were stored in an electronic database using Reference Manager 11.0 (ISI Research Soft Inc, Berkeley, California). Two reviewers independently assessed whether these studies met the following inclusion criteria: (i) the study included a CEA and/or CUA, (ii) participants were part of the adult working population, (iii) the intervention under study was a WHP program aimed at improving nutrition and/or increasing physical activity, (iv) the intervention was compared to usual care (including no intervention) or an abridged version of the program, (v) outcome measures included a behavioral measure (eg, physical activity and dietary intake), a health-related measure (eg, BMI, waist circumference, body fat percentage, musculoskeletal symptoms, cardiorespiratory fitness, and health risk profiles), or a work-related measure (eg, productivity and work satisfaction), and (vi) the study was reported in English, German, French, or Dutch.

For the purpose of this review, analyses could be performed from all perspectives (eg, employer’s perspective and societal perspective). Furthermore, no limitations were set as to program format [eg, (self-)assessment, counseling, and exercise program], worksite characteristics (eg, age, gender, occupation, proportion of full-time employees, and number of employees), length of the intervention, and follow-up duration. Studies aimed at long-term sick-listed employees, employees with chronic conditions (eg, diabetes type 2 and CVD), retirees, and children were excluded. If studies met the inclusion criteria, or if uncertainty remained about inclusion, fulltexts were retrieved. All fulltexts were read and checked for eligibility. To resolve disagreements between the two reviewers, a consensus procedure was used. A third reviewer was consulted when disagreements persisted; this was necessary on one occasion.

Risk of bias assessment

Two reviewers independently assessed the risk of bias of included studies. If one of the reviewers was a (co-)author of a given study, another reviewer acted as the second reviewer. Risk of bias was assessed using the Consensus Health Economic Criteria list (CHEC-list), which was developed for systematic reviews of economic evaluations using a Delphi consensus procedure involving 23 international experts in economic evaluations (43). The test–retest reliability of the CHEC-list was shown to be good (intra-class

correlation coefficient: 0.97, 95% CI 0.73–0.98) (44). Items were scored as negative in case of an inadequate performance of an item or if insufficient information was available in the article or related materials (43). If a study presented its results in multiple articles, those articles were scored as one study. A consensus procedure was used to resolve disagreements between the two reviewers. When disagreements remained, a third reviewer was consulted; this was necessary on two occasions.

Data extraction, data analyses, and applied classification schemes

Data were extracted on: (i) study details (eg, perspective, primary study design, setting, and follow-up duration), (ii) characteristics of the study population (eg, participant and job characteristics), (iii) program focus (ie, improving nutrition, increasing physical activity, or both), (iv) program format [ie, (self-)assessment, educational/informational, behavioral, exercise, environmental, and incentive components], (v) measurement and valuation methods of costs, (vi) measurement methods of effects, and (vii) study results [reported costs, effects, and incremental cost-effectiveness ratios (ICER)]. One reviewer extracted data using a pre-designed data extraction form. Ten percent of the extracted data was checked by a second reviewer, which did not reveal any errors. If articles did not contain sufficient information on study results, authors were contacted for missing data.

If an incremental cost-effectiveness analysis was not performed, an ICER was calculated per reported outcome measure as the incremental difference in costs relative that in effects (30). Costs and ICER were standardized to 2010 US dollars (USD) using consumer price indices (45) and purchasing power parities (46). For this, their reference year was needed. If their reference year was not stated, the year of publication was used. For data analyses and presentation, studies were grouped according to their program focus (ie, improving nutrition, increasing physical activity, or both), (stated) perspective, and outcome measures.

To summarize results, and thereby draw conclusions about the cost-effectiveness of the included programs, their incremental costs and effects were explored. Programs that were less costly and more effective than the control condition were considered cost-effective (ie, the program dominates the control condition). For programs that were more costly and less effective, the opposite was true. Programs that were either more costly and more effective or less costly and less effective were only considered cost-effective if their ICER was respectively lower or higher than the “willingness to pay” (ie, the maximum amount of money decision-makers are willing to pay per unit of effect gained) (30).

Results

Literature search and study selection

The electronic search yielded 3230 unique references. After screening their abstracts and titles, we retrieved 47 fulltexts. Thirty-one additional fulltexts were retrieved after screening references of relevant review articles and those of the retrieved fulltexts. After reading those 78 fulltexts, 9 articles were identified that met the inclusion criteria (figure 1). Additionally, three unpublished articles were identified by searching the authors' own literature databases. Contacting authors of included studies did not yield any additional results. Most studies were excluded because they did not include an economic evaluation or because they only evaluated the financial return by comparing intervention costs to their financial consequences. Eventually, 12 articles, including 10 original studies (47–58), were included in the review.

Study characteristics

A description of the study characteristics can be found in table 1. Worksite nutrition programs (N=7) were evaluated in four studies (47, 51, 55, 56) and worksite physical activity and nutrition programs (N=11) in six studies (48–50, 52–54, 57, 58). None of the studies evaluated a WHP program solely aimed at increasing physical activity. In general, interventions consisted of a (self-)assessment, educational/informational, behavioral, exercise, environmental, and/or incentive component. All interventions were compared to usual care, consisting of no intervention or a (self-) assessment, educational/informational, and/or environmental component. The number of participants in the studies ranged from 66–1883. The length of the interventions ranged from 12 weeks to 3 years. Four studies (51, 54–56) evaluated the short-term effectiveness of the programs (follow-up ≤6 months) and six studies (47–50, 52, 53, 57, 58) evaluated the long-term

effectiveness (follow-up >6 months). No studies had a follow-up >3 years. Seven studies (47–50, 52–54, 57, 58) were conducted alongside a randomized controlled trial and three (51, 55, 56) alongside a non-randomized study. Five studies (47–49, 51, 54, 56) were conducted in the US, three (50, 53, 57, 58) in the Netherlands, one (52) in Australia, and one (55) in Denmark. All studies conducted a CEA, and one (58) also conducted a CUA.

Risk of bias assessment

Reviewers initially disagreed on 40 (21%) of the 190 items (10 studies multiplied with 19 CHEC-list items). Most disagreements were due to reading errors and different interpretations of the CHEC-list items and were solved during the consensus meeting; for four disagreements a third reviewer was consulted. Of the 19 CHEC-list items, 11 (58%) were fulfilled by more than 50% of the studies and 7 items (37%) by more than 75%. The economic perspective was specifically stated by four studies (50, 53, 54, 57, 58), including: the societal perspective, the employer's perspective, and that of an implementing agency. The latter (54) appropriately collected costs to the chosen perspective by only including intervention costs. Studies performed from the societal and employer's perspective also included absenteeism and/or medical costs and were all conducted in The Netherlands.

Costs were measured in physical units [ie, individual items of an intervention were measured (30)] in four studies, (52–54, 57, 58). One of them (54) also appropriately valued costs by calculating them based on depleted sources [ie, based on the value of the forgone benefits because the resources were not available for their best alternative use (30)] and stating their reference year. Three studies (47, 51, 56) presented both costs and effects, but did not conduct an incremental cost-effectiveness analysis. Just over half of the studies conducted a sensitivity analysis to test the robustness of their results (table 2).

Cost effectiveness analysis

Worksite nutrition programs. All four studies (47, 51, 55, 56) evaluating WHP programs aimed at improving nutrition only included intervention costs in their cost estimates (table 3). Two of them (51, 55) evaluated cost-effectiveness by comparing intervention costs to the effect on body weight reduction. Both interventions were more costly and more effective than usual care at a cost of \$43 and \$20 per kilogram body weight loss (see also table 4). One of those (55) was also more costly and more effective in reducing daily fat intake and increasing daily carbohydrate intake. The other intervention (51) was also more costly and more effective in improving physical functioning, general health,

Table 2. Risk of bias assessment of included studies using the Consensus on Health Economic Criteria list (CHEC-list).

CHEC-list items	Studies scoring	
	N=10	
	N (Yes)	%
1) Study population	7	70
2) Competing alternatives	9	90
3) Research question	5	50
4) Study design	10	100
5) Time horizon	9	90
6) Perspective	3	30
7) Costs identified	1	10
8) Costs measured	4	40
9) Costs valued	1	10
10) Outcomes identified	9	90
11) Outcomes measured	8	80
12) Outcomes valued	10	100
13) Incremental analysis	7	70
14) Discounted	7	70

16) Conclusions	10	100
17) Generalizability	1	10
18) Conflict of interest	2	20
19) Ethical and distributional issues	0	0

vitality, mental health, impairment at work, and impairment with daily activities. However, the intervention was more costly and less effective in reducing restraint, disinhibition (ie, overeating in response to stress or other cues), and hunger.

Two other studies (47, 56) evaluated cost-effectiveness by comparing intervention costs to the effect on cholesterol level reduction. However, both studies used different outcomes for assessing the degree of cholesterol level reduction, which limits their comparability. The first study (56) evaluated four different interventions (I): (i) I-1: 1-month program without incentives, (ii) I-2: 1-month program with incentives, (iii) I-3: 3-month program without incentives, and (iv) I-4: 3-month program with incentives. The least intensive program (ie, 1-month program without incentives) was more costly and less effective than usual care (ICER: \$-110 per 1% of participants reducing their cholesterol level by $\geq 10\%$). The other interventions were more costly and more effective (ICER I-2: \$0.1; I-3: \$4; and I-4: \$54). The nutrition intervention evaluated by the second study (47) was also more costly and more effective than usual care at a cost of \$11 per 1% cholesterol level reduction.

Worksite physical activity and nutrition programs

Six studies evaluated the cost-effectiveness of WHP programs aimed at increasing physical activity and improving nutrition (48–50, 52–54, 57, 58). Three of them (48, 49, 52, 54) only included intervention costs in their cost estimates. When costs were considered from a broader perspective (50, 53, 57, 58), intervention costs

were partially offset by a reduction in absenteeism and/or medical costs (table 3).

Three studies (50, 54, 57, 58) evaluated the cost-effectiveness in terms of body weight reduction from various perspectives. All interventions were more costly and more effective than usual care. When only intervention costs were considered, the additional costs per kilogram body weight loss were \$26. When analyses were performed from the employer's perspective those costs were \$75 and \$1534, and from the societal perspective \$174, \$20, and \$1282 (see also table 4). One of those interventions (54) was also more costly and more effective in reducing waist circumference.

Two other studies (48, 49, 52) evaluated the cost-effectiveness by comparing intervention costs to the effect on CVD risk reduction. Both studies, however, used different composite scores to estimate the level of CVD risk reduction, which limits their comparability. The first study (52) evaluated three different interventions: (i) I-RFE: risk factor education, (ii) I-BC: behavioral counseling, and (iii) I-BCI: behavioral counseling plus incentives. All interventions were more costly and more effective than usual care (ICER I-RFE: \$10, I-BC: \$24, and I-BCI: \$363 per CVD risk unit reduced). The other study presented its results in two articles (48, 49), which differed in the number of CVD risk factors included in the composite score (ie, three risk factors in the first article versus four in the second article) as well as their control condition. Furthermore, in the first article (48), they did not include all intervention costs in their cost estimates (ie, fitness centre costs were missing). In the second article (49), they evaluated three different interventions: (i) I-FC: fitness centre, (ii) I-HEC: health education & follow-up counseling, and (iii) I-HECE: health education, follow-up counseling & environmental strategies. I-FC was more costly and less effective than usual care. The other interventions were more costly and more effective (ICER I-HEC: \$2 and \$2 I-HECE: \$3 and \$3 per 1% of CVD risks, respectively highly or moderately reduced).

Another study (53) evaluated the cost-effectiveness from the employer's perspective using its effect on physical activity-related outcome measures. The intervention was more costly and more effective than usual care in increasing energy expenditure, and decreasing sub-maximal heart rate. However, the intervention was more costly and less effective in increasing the number of participants meeting physical activity recommendations.

Cost-utility analysis

One study (58) evaluated the cost-utility of both an internet- and a phone-based nutrition and physical

activity program. Analyses were conducted from the societal perspective. After 24 months, the cost-utility of the internet-based intervention was \$1698 per quality-adjusted life year (QALY) gained and that of the phone-based intervention \$311 523 per QALY gained.

Discussion

The present review critically appraised and summarized the current evidence on the cost-effectiveness of worksite physical activity and/or nutrition programs. Ten studies (published in 12 articles), evaluating 18 programs, were included in the review.

None of the studies evaluated WHP programs aimed solely at increasing physical activity.

From various perspectives, worksite nutrition as well as worksite physical activity and nutrition programs (N=6) were more costly and more effective in reducing body weight compared to usual care during the first years after implementation. If only intervention costs were considered, most worksite nutrition (N=4/5) and worksite physical activity and nutrition programs (N=5/6) were more costly and more effective in reducing cholesterol level and CVD risks, respectively. Currently, however, there are no set levels for how much different stakeholders are willing to pay for reductions in body weight, cholesterol level, and CVD risks. It is therefore unknown whether the costs associated with achieving these results are acceptable, ie, whether these programs are cost-effective. Therefore, it is up to individual decision-makers to judge whether or not these programs offer value for money.

CEA were also conducted in terms of various other outcome measures (eg, dietary habits, quality of life, physical activity-related outcome measures, and work-related outcome measures). However, ICER in terms of these outcome measures were only calculated for one intervention. Furthermore, only one study evaluated the cost-utility of worksite physical activity and nutrition programs and provided mixed results. When compared to the National Institute for Health and Clinical Excellence (NICE) threshold of GBP20,000 (\pm USD30 500) to GBP30 000 (\pm USD45 700) per QALY gained as well as the frequently cited US threshold of USD50 000–100 000 per QALY gained (59), the internet-based intervention of the study can be regarded as cost-effective (\$1698 per QALY gained), whereas the phone-based intervention (\$311 523 per QALY gained) cannot. All in all, these findings do not necessarily support the conclusion of a previous review (36) that the literature provides “guarded cautious optimism” about the cost-effectiveness of WHP programs.

When only intervention costs were considered, the additional costs per kilogram body weight loss ranged from \$20–43, independent of the program focus (ie, nutrition or physical activity and nutrition). From a broader perspective, intervention costs were partially offset by a reduction in medical and/or absenteeism costs. Strikingly, this did not result in lower ICER as the three programs evaluated by only including intervention costs were equally or more effective in reducing body weight compared to those evaluated from a broader perspective, whereas their intervention costs were similar or lower. This superior effectiveness might be explained by the fact that these studies conducted follow-up measurements immediately after the intervention period (<6

^b Incremental cost-effectiveness ratio calculated based on the information provided in the article and related materials.

months) as opposed to several months after the completion of the program (≥ 6 months) in the studies performed from a broader perspective. Systematic reviews show that (partial) weight rebound after the intervention period is common (60, 61). Another explanation may be the non-randomized design of two of these three studies (ie, results may be confounded by selection bias) (40). Nevertheless, it would also be insightful to investigate the relationship between intervention costs, which are strongly related to intervention composition and intensity, and effect size in more detail. If it is established that more costly programs do not necessarily produce better health outcomes or cost-savings, cost containment strategies during the design phase of a program may be a useful strategy to optimize cost-effectiveness.

A risk of bias assessment revealed that most of the included studies had several methodological shortcomings. For example, few studies specifically stated their perspective and an incremental analysis of costs and effects were not performed in all studies. Furthermore, many studies applied a rather restrictive perspective by only including intervention costs in their cost estimate. However, as WHP programs are thought to be associated with other cost categories (eg, medical and productivity-related costs) (27), the adoption of a broader perspective is recommended. Costs were only measured in physical units in four studies, and of these, only one valued them appropriately by calculating them based on depleted sources and stating their reference year.

Furthermore, although research has indicated that presenteeism accounts for a larger proportion of productivity-related losses compared to absenteeism, none of the studies conducted from the societal and/or employer's perspective included presenteeism costs in their cost estimates. This likely resulted from the fact that a "gold standard" for measuring and valuing presenteeism does not exist. Nevertheless, up until now, various instruments have been developed to measure presenteeism, of which several capture lost productivity suitable for direct translation into a monetary unit (62–64).

In addition, although economic analyses require that assumptions are made (30, 65), few studies conducted a sensitivity analysis and hardly any of the studies reported on the uncertainty around their ICER. Sensitivity analyses are useful to test the robustness of the study results, but do not give insight into the uncertainty due to sampling variation (30, 66, 67). To quantify precision, non-parametric bootstrapping can be used as a statistical technique for dealing with the highly skewed nature of cost data (30, 65) and the uncertainty around an ICER can be illustrated graphically using cost-effectiveness planes (30). It is also important to mention that three studies did not even report on the uncertainty around their effect sizes. Economic evaluations rely heavily on the assessment of the clinical effectiveness (30).

Not reporting on the uncertainty around the effect sizes strongly hampers the interpretation of the reported ICER. Using results of economic evaluations with a high risk of bias for deciding how resources should be optimally allocated, may lead to inappropriate decisions (40, 65). Therefore, strong conclusion about the cost-effectiveness of worksite physical activity and/or nutrition programs cannot be made due to the methodological shortcomings of the included studies. This should be addressed in future studies. In particular, future studies should include presenteeism costs and emphasis should be placed on the handling of uncertainty.

One of the main strengths of this review was that it incorporated a risk of bias assessment using a standardized quality checklist based on consensus among experts in the field of economic evaluations. Furthermore, four additional studies were identified compared to previous reviews on the cost-effectiveness of WHP programs, all of which evaluated costs and kilogram body weight loss. As a result, the present review was the first to compare ICER in terms of costs per kilogram body weight loss from different perspectives. However, due to heterogeneity of outcome measures, follow-up (long- versus short-term), and perspectives, results could not be pooled. As a result of the relatively limited number of included studies, it was also not possible to conduct subgroup analyses to investigate the impact of program format [ie, (self-)assessment, educational/informational, behavioral, exercise, environmental, and incentive components] or participant characteristics (eg, age, gender, and white- versus blue-collar workers) on the cost-effectiveness of the interventions.

Therefore, the present review cannot indicate which program formats are important for attaining cost-effectiveness or how worksite physical activity and/or nutrition programs should optimally be designed. Furthermore, a program's cost-effectiveness may depend on the characteristics of its participants. Blue-collar workers, for example, may respond differently compared to white-collar workers as a result of their difference in underlying health risks (68). It is important to address these issues in future reviews when additional research on the cost-effectiveness of worksite physical activity and/or nutrition programs has been completed.

Another limitation of the present review was the possible effect of publication bias. That is, economic evaluations may be more likely to be conducted of interventions that had previously been found to be effective, and studies with favorable results may be more likely to be published. It is also important to bear in mind that all CEA conducted from the employer's perspective were performed in The Netherlands. These results are not necessarily generalizable to other countries, as their health and social security systems may differ. US employers, for example, bear

a large part of the medical costs of their employees, whereas in Europe these accrue to the government and/or insurance companies (28). Furthermore, only trial-based economic evaluations with relatively short follow-ups (≤ 3 years) were identified and included. As cost-savings due to improved health might only occur after a longer period, this may have resulted in an underestimation of a possible absenteeism and/or medical cost-offset effect. Due to their relatively short follow-ups, studies were also only able to assess the programs' cost-effectiveness in terms of intermediate outcome measures relating to aspects of diet and physical activity (eg, CVD risk, body weight, and cholesterol level reduction), whereas disease prevention (eg, CVD, diabetes type 2) can be regarded as the primary endpoint of worksite physical activity and/or nutrition programs (69). To bridge the gap between what has been observed in the trial-based economic evaluations and what the cost-effectiveness of worksite physical activity and/or nutrition programs would be over a longer time horizon, decision analytic modeling could be used (30). However, currently little is known about the longevity of the intermediate outcomes of WHP programs and the relationship of these outcomes with changes in long-term medical and productivity-related costs. More research should be done in this field to allow for the development of credible decision analytic models.

Concluding remarks

Current evidence indicates that worksite physical activity and/or nutrition programs can result in reductions in body weight, cholesterol level, and CVD risks, but at a higher cost than usual care. Because it is unknown how much decision-makers are willing to pay for these health outcomes, conclusions about their cost-effectiveness cannot be made. Most of the included studies had several methodological shortcomings, which hinders the validity of their results. Therefore, there is substantial need for improvement of the methodological quality of studies evaluating the cost-effectiveness of worksite physical activity and/or nutrition programs and particular emphasis should be placed on the handling of uncertainty.
